It is still too early to say what success the Act and the instrumentalities it creates—the United States Railway Association (*USRA*) and the Consolidated Railway Corporation—will have in ending the exploitation of the common carrier obligations imposed by the Interstate Commerce Act. While some pruning of rail operations in the Northeast has been spoken of, hearings held throughout the region have revealed strong political opposition to service cutbacks of any kind. The representation of shippers, states, cities, rail labor, and the Interstate Commerce Commission on the Board of Directors of *USRA* suggests that meaningful reform on this front can be little more than a hope.

There are, on the contrary, disturbing signs that we are being prepared for an assault on the public purse to get us past this crisis. Any employee whose job is eliminated will be generously protected by public funds, according to the Act, though there are few if any precedents for public protection of workers who have lost jobs when the fortunes of an industry have turned. Branch line subsidies will preserve "essential rail service" along rail lines that might otherwise be abandoned, though the decline of traffic on these lines is itself evidence that rail service is no longer essential to more than a few shippers. Fixed rail plant is to be rebuilt with federal grants and loan guarantees.

One can even hear the rhetoric that is to prepare us for continuing subsidy of Northeast rail operating deficits after these initial excuses—labor protection, branch-line subsidies, etc.—begin to pall. The railways, we are told, are a "valuable natural resource," the "low-cost carrier," a "fuel-conserving mode of transport." Is it cynical to ask why, if railroads are so inherently efficient, have they sunk to their present state and why must they be subsidized and protected from higher-cost competitors? Judging from present deficits, the drain of the Northeast rail system on public funds will run on the order of $500 million to $1 billion annually even at the onset.

But the present drift of events will almost certainly carry us further than nationalization of Northeast railroads. Clever, solvent rail carriers may find it profitable to encourage federal involvement and public subsidy for the bankrupt railroads. Freight cars today absorb over half of all rail capital expenditures. The Penn Central, western and southern carriers claim, has long beggared other railroads for freight cars because of its own inadequate ownership. What an opportunity to reverse the score now that the public treasury will be buying cars. The argument for branch-line subsidies does not lose validity at the Potomac, Ohio, and Mississippi Rivers; once the principle is accepted for the Northeast, solvent carriers should be able to tap easily into a branch-line subsidy program.

Then look further to the future. The entire American railroad industry has earned a subnormal return on invested capital for decades. Net railway operating income in 1973, a good year, was one-third lower than in 1929, without adjustment for the greatly reduced purchasing power of those dollars. The railroads' rate of return on transportation investment has not exceeded 5 percent since 1929 and has not exceeded 4 percent since 1955. Railroad executives constantly face a difficult decision in committing and recommitting capital to an enterprise whose return has been so marginal for decades, particularly now that interest rates have risen to the 10 percent level. With the low returns and the vast appetite for capital that railroads have, the owners may welcome a chance to unload the business, if only some sucker may be found to buy it. The settlement with the creditors of the Northeast bankrupts may set the terms at which the owners of solvent railroads can expect to sell out. While the Regional Rail Reorganization Act may not have intended it, it appears that the courts may award the estate reasonable value for any properties taken over. Once management of solvent carriers decides that liquidation of rail assets and ultimate sale of the remains to the government are more attractive than perpetual reinvestment for inadequate returns, the properties of these carriers will begin the long slide into disrepair, down the same track as the Northeast bankrupts.

Other industries may some day find it attractive to play the same game. Once the government commits itself to solving industrial crises like the Northeast rail situation and doing so from the public purse, an important restraint upon the demands of other interest groups in the economy will have been sacrificed. Already several large airlines have applied, though unsuccessfully to date, for Federal subsidies. Distant early warnings of trouble in the electric utility industry have also appeared. Is it time to ask what precedents we wish to set?

Transportation Controls and the Spatial Structure of Urban Areas

By GERALD S. GOLDSTEIN AND LEON N. MOSES*

The nineteenth century city in America relied upon rail transportation, the horse-drawn streetcar, as the primary mode of travel to get people to and from work. In the twentieth century city the automobile replaced the streetcar as the dominant mode for commuters. Traffic congestion, air pollution, noise pollution, urban blight, and "wasteful" use of gasoline have been attributed to the growing use of automobiles, particularly for the work trip. Transportation policies that would encourage the use of public mass transportation relative to the private automobile have been proposed by public interest groups and government agencies, such as the Environmental Protection Agency, in order to alleviate some or all of these problems.

The analysis in this paper will focus on the long-run effects of transportation policies that affect the cost of automobile travel versus mass transit on the spatial distribution of households. In the long run households can adapt to such controls by moving their residences, and/or their places of work. A basic urban land-use model developed by urban economists will be adapted to explore the long-run changing patterns of land use. Inferences must be drawn from a partial equilibrium approach, since there does not exist a static model of the city in which the intraurban location of firms and households is simultaneously determined.

Formal economic models of the city have focused predominantly on the spatial distribution of households. In these models all production and employment are located in a central point through which all imports and exports move. This point is assumed to be located on a featureless plain on which transportation is ubiquitous. The population is composed of households with identical utility functions who bid for land around the central point, the central business district (*CBD*). The cost of building and maintaining houses (excluding site rent) is constant throughout the city.

In equilibrium all households must achieve the same utility level. Since all jobs are located in the *CBD*, people who live some given distance from the *CBD* must pay higher costs of transportation to get to the *CBD* than people who are located nearer to the *CBD*. Because of the equilibrium condition, and the assumption that transportation costs are positive and increase with distance from the *CBD*, those households who live near the *CBD* must pay higher rent per unit than those households living farther away. In equilibrium, the price per unit of housing must decline with distance from the *CBD* so that what the household saves in housing costs by moving further away from the *CBD* must just be offset by the increase in costs of getting to the *CBD* as a result of the move. A further implication of this model is that population density will decline with distance from the *CBD*, the rate of decline depending on the rent gradient.

---

Research support from the Motor Vehicle Manufacturers Association is gratefully acknowledged. The views expressed are ours and not necessarily those of the association.

The higher is site rent at any given location, the higher population density will be.

There is one modification to this basic model which is of interest here. We introduce the additional assumption of local employment opportunities uniformly distributed throughout the area. The *CBD* remains the dominant source of employment opportunities. The implication of this modification is that there will be a wage gradient, analogous to the rent gradient. The basic explanation of this wage gradient is the same as that for the rent gradient. Because household equilibrium requires equalization of household utility throughout the area, people who live and work outside the *CBD* must earn less than people who live at the same location but work in the *CBD*. If they both received the same wage, then the worker working outside the *CBD* would earn a higher real income since he would not incur the transportation costs of the *CBD*-worker, but would pay the same price for all other goods.

We turn now to the long-run effects of transportation controls on urban spatial patterns. We must consider the influence of alternative modes of transportation on wage, rent, and price gradients. This issue must be faced since a variety of transportation controls are designed to increase the cost of auto relative to public transportation. Further, a new dimension, choice of work area, must be added. We will assume two employment centers, the core and a suburban center. The wage rate for a particular kind of skill is assumed to be higher in the core than in the secondary center. A very dense system of public transportation, perhaps bus, is assumed to exist around the core. Workers have three choices: (1) to live within the bus commuting area and use the bus to commute to the core; (2) to live outside the bus commuting area, but commute to the core for work by car; (3) to commute to the secondary center by car.[1] The situation is depicted in Figure 1 where O is the core, and A, the secondary employment center.

The solid circle around the core is the limit of the bus commuting area. Those who live on the boundary are indifferent between going by bus to the core and going by car; those inside the circle commute by bus, and those outside it commute by car. The circle represents the results of a situation in which in a sense there is complete coverage of the inner area by bus routes and the bus is less expensive in money terms than the car, but requires more time. In addition the downtown parking fee is greater than the round-trip flat bus fare.[2]

The car commuting area is divided into two zones by the hyperbolic market boundary UU'. Those who live on UU' are indifferent between traveling to the core for work and traveling to the secondary center for work. They are indifferent because the real income they achieve is the same regardless of the choice they make. Individuals who live inside the boundary UU' commute to the secondary labor market by car.

The analysis begins with all households in equilibrium defined above to mean that no household can improve its level of satisfaction by changing its place of work, residential site, or mode of transportation. In addition, all land markets are cleared. A change is now made in the cost of transportation. Two broad alternatives are considered. The cost of travel by car is increased or the cost of public transportation is reduced. These changes can be brought about in a variety of ways. The impacts of most of them on the wage and rent gradients differ only in detail. However, an in-

---

[1] The model has been constructed to eliminate choices that would add complexities, but which would add little to the problem being investigated. As constructed, the problem eliminates cross-hauling and what is often called back-commuting, i.e., commuting to the secondary center by people who live close to the core.

[2] If the per mile cost, including the value of time, is less by car than bus, there is no bus area.

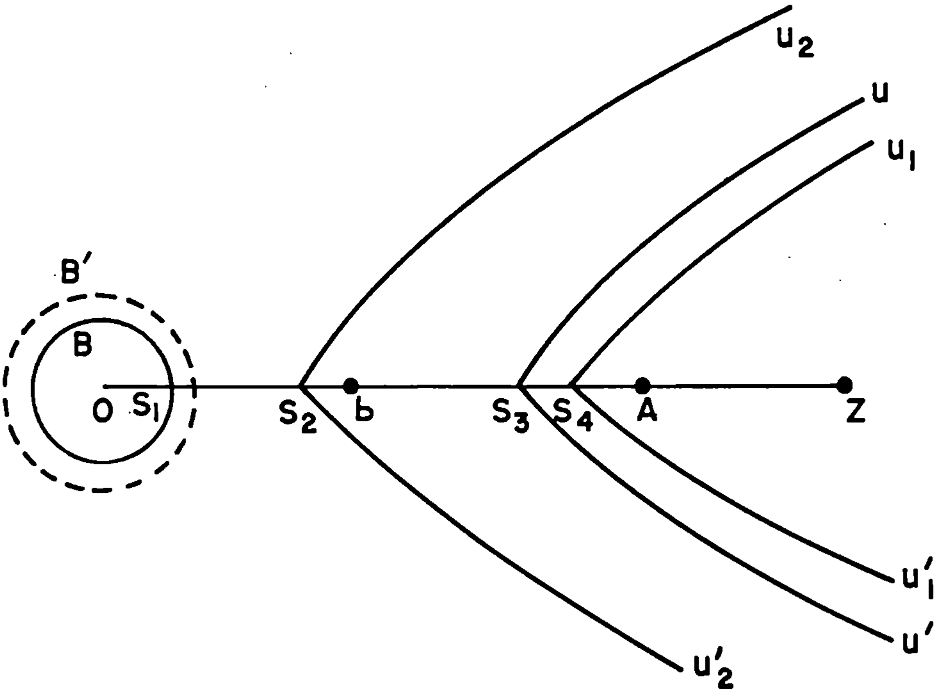

Figure 1

crease in downtown parking charges or in tolls does have somewhat different implications from an increase in the per mile cost of auto travel. Therefore these measures must be studied separately.[3] The effects of different measures that improve the attractiveness of public transportation also differ somewhat, but here the differences are insignificant.

Overall, the procedure followed is to change the quality of the public transportation system and examine its effects on the wage gradient and the household bid-rent function. Implications of the public transportation improvement for the new equilibrium distribution of population and economic activity are then sought. The same line of reasoning is then worked out for an increase in per mile auto costs and the effects are compared.

The quality and cost characteristics of public transportation can be improved in a variety of ways. There is no need to consider all of them since they appear to have very similar effects. We deal with a case in which an express bus is introduced whose time and cost characteristics make it an attractive alternative to the car for a certain set of households. The initial impact of the new service on choice of mode is represented in Figure 1. The express bus service is assumed to operate in the automobile commuting area. So far as the analytical model is concerned, it does not matter where the station is located. It can be somewhere on a line different from *OZ*, in the secondary center itself, or on the line *OZ* and between *O* and *A*. The latter is assumed. *b* is the station.

The introduction of express bus service makes it cheaper in time, money, or disutility of travel to commute to the core by bus. It thereby raises the net wage that can be earned by working in the core. This causes the boundary UU' to shift to the position shown by U_1U_1'. In the short run households that live in the area between these two boundaries continue to work in the secondary employment and commute by car. In the long run they may change place of employment and place of work. Initially it is assumed that they are satisfied with their residential area and seek to adjust to the change in transportation by changing place of employment.[4] The effect of the new service is to raise the labor supply function of the core and reduce the labor supply function of the secondary center and any other actual or potential employment centers in the automobile commuting area. The statement made above concerning the two labor supply functions can be phrased differently. The new service causes the individuals who live between UU' and U_1U_1' to search for jobs in the core. It also increases the wage rate that they would demand at the secondary center and at all places within this area between UU' and U_1U_1'.

---

[3] The effect of these measures and their impact on decentralized cities as well as on monocentric cities is studied in greater detail in Goldstein and Moses, "Air Pollution, the Clean Air Act, and the Spatial Structure of Urban Areas," mimeo. 1974.

The express bus also opens up a second choice for those who have been commuting to the core by car. This choice is represented by U_2U_2'. Individuals who live to the right of this boundary and to the left of UU' find that their net incomes are higher if they shift from car to the new service. If they are satisfied with their neighborhoods, the effect of the improvement is to increase the wage rate that they would demand for working nearer home, or anywhere in the satellite area as an alternative to continuing to work in the core. This means that the wage gradient shifts up in the satellite area between UU' and U_2U_2', which is to say that there has also been a downward shift in the labor supply function of any actual or potential employment site in this part of the satellite area.

Households who live to the left of U_2U_2' and outside the bus circle continue to travel to the core by car. Nevertheless, their costs of travel may be affected by the new service. If their costs change, their choice between working in the core and working nearer home or at other potential employment sites in the area will be affected. Suppose that the introduction of the new bus service reduced automobile congestion in and around the core because some workers have changed to bus. This will reduce the cost of automobile commuting to the core for workers who live to the left of U_2U_2' and make labor supply conditions less favorable in the automobile commuting area. In other words, the minimum wage individuals will accept for employment in their part of the satellite area is increased.

Finally we consider the individuals who live in the local bus circle. They are not directly affected by the new service. The reduction in automobile commuting to the core from other areas might increase the speed and convenience of local service, but this is unlikely to be a strong effect. The wage gradient in this area is therefore treated as unchanged.[5]

Over the largest part of the former automobile commuting area, labor supply conditions for local employment have become less favorable. In addition, land in the area has become more valuable for households who commute to the core for work. These two changes may make the area less desirable as a location for those kinds of industry, such as manufacturing, where single floor layout is valuable and large amounts of space are used. It seems likely that an improvement in public transportation would act to make the automobile commuting area a less favorable location for many kinds of industry. It would certainly not contribute to a more rapid rate of business migration from the central city. However, as population expands in the area around the station, retail as well as some service activity, such as insurance and banking, might be expected to grow.

---

[4] This assumption obviously alters the traditional model of urban location. In effect we are introducing neighborhood effects and saying that access to work is not the sole determinant of residential location.

[5] The conclusions reached would not be altered significantly if local service did improve as a result of the introduction of express service. In this case, the households who live in the bus area of the central city are less willing to work nearer home and outside the *CBD*.

The area in the vicinity of the secondary employment center has become relatively less valuable for households. This means that industry could acquire additional land at less cost. Industry has some incentive to expand in the area. On the other hand, labor supply conditions have become less favorable. It is not possible to judge the relative strength of the two changes. However, if the secondary center does not have advantages such as access to low-cost interregional transport facilities, it is unlikely to grow rapidly as an employment center. The effects of an increase in the cost of automobile travel will now be considered.

This cost can be increased in a variety of ways. Consider first the effects of an increase in the per mile costs of such travel, not bothering to distinguish between an increase due to a transportation measure or a market increase in the price of gasoline. There has been a tendency to view increases in automobile travel costs as having the same implications as improvements in public transportation. In the short run both have the effect of causing diversion from car to public transportation. However, the long-run effects on the distribution of population and economic activity are likely to be quite differferent. Improvements in public transportation are likely to slow the rate of outmigration of industry from core areas and central cities generally. Increases in the cost of auto travel are very likely to cause core areas and central cities to decline more rapidly.

An increase in the per mile cost of auto travel causes a shift from car to local bus. This is represented as an increase in the bus zone from B to B', in Figure 1. Individuals who live between the two circles have been made worse off, the amount of their reduction in real income increasing with distance from the core. These individuals are more willing than before to work at sites closer to their homes and more accessible by car. This means that the labor supply function of the core has decreased and the labor supply functions of actual and potential employment sites in the zone between the two circles have increased.

The increase in auto travel cost also shifts in the boundary UU' to the position U_1U_1'. In the short run the individuals who live between the two boundaries cannot change their place of residence or employment. However, they have suffered reductions in their real incomes. The farther they live from the core the greater is the amount of the reduction. If we treat residences as fixed for the moment, it is clear the individuals who live between the two boundaries are more willing to work at sites that are nearer home. This means that they are willing to accept lower wage rates than before for employment at such sites. Labor supply conditions then are less favorable in the core because its labor supply function has shifted down.

The individuals who live to the right of UU' continue to work in the secondary center, but they have also suffered a reduction in real income. The further they live from the secondary center, the greater the amount of the reduction. They would also like to work closer to home.

Overall, if households react to an increase in auto travel costs by searching for jobs from their given residential sites, the effect is to improve labor supply conditions in suburban residential areas. This area includes that segment where individuals have shifted to bus. The effect of the increase is to make labor supply conditions in the central city less favorable. This change in labor supply conditions will clearly increase the relative attractiveness of noncore sites for industry.

Some additional comments are necessary. Households who live in the original bus area, an area corresponding roughly to the central city, have not experienced a change in real income while all other households are worse off. In this situation it can be argued that city living has improved relatively, and that the improvement will cause individuals to return to the city. We do not believe that such a remigration will occur. Hence, we are saying that such readjustments as take place in residential settlement will not change the generally adverse impact that an increase in auto travel costs is likely to have on labor supply conditions in the central city. Consider now the possible implications of an increase in auto travel costs on the value of space.

An increase in the per mile cost of auto travel reduces the net money income of households over the entire automobile commuting area. Overall, the effect of such a reduction should be to decrease what households can bid for residential space and thereby make space cheaper for industry. In other words, taking the automobile commuting area as a whole, the increase in travel costs is likely to have an impact on land values that reinforces its effect on labor supply conditions. The attractiveness of the satellite area for industry is increased still further. The above is not meant to preclude the possibility that there will be changes in relative land values over the satellite area. We cannot judge this, again because it is not possible to say anything definite about the new long-run equilibrium and the pattern of jobs and households that will emerge in the satellite area. If individuals' commuting costs go up substantially, but truck transport costs do not increase very much, we are likely to see a broad dispersal of economic activity. There would be a tendency for many small employment centers to emerge, each drawing labor from a relatively localized area. However, if truck costs rise substantially, there will be a tendency for larger employment centers to develop, particularly in those portions of the satellite area that have good access to low cost interregional transport facilities.

I. Summary and Conclusions

This paper has examined the long-run effects on cities of changes in the cost of moving people. Two kinds of policies are compared: (1) those that increase the cost of travel by car, and (2) those that improve the quality or reduce the price of public transportation. The paper argues that the former are likely to reduce auto travel more quickly. However, these policies are also more likely to cause the economies of central cities to decline more rapidly than they would otherwise. A policy of improving and subsidizing public transportation would tend to slow their rate of decline. So far as the economies of central cities are concerned, there is a set of measures that appears to be most damaging. These are the ones that increase the cost of auto travel to central cities or their core areas relative to the cost of auto travel elsewhere in standard metropolitan statistical areas. Reductions in the supply of downtown parking, special taxes on such parking, tolls to the downtown area, etc. are examples of such measures. Unfortunately, since funds for improvements in public transportation almost certainly must come from taxes, there may be an inclination to rely on such measures to achieve air quality in large central cities.

Regulation and the Financial Condition of the Electric Power Companies in the 1970's

By Paul L. Joskow and Paul W. MacAvoy*

Electricity accounts for about 25 percent of the total energy consumed in the United States and its share of total consumption has been increasing slowly. In an effort to decrease the vulnerability of the United States to foreign energy price increases and embargoes, Federal energy policy, particularly as formulated in the *Federal Energy Administration Report for Project Independence*, would accelerate this trend towards electricity. These policies call for the mandatory conversion of household and commercial heating to electricity and the conversion of oil- and gas-burning plants to domestically available coal and uranium. Even without such mandatory controls, consumers may choose more electricity as a result of increases in fuel oil prices relative to electricity prices, or as a result of the shortage of natural gas, or because electricity supply seems more secure.

Although Federal policies and consumer choice may shift demands towards electricity, there is no assurance that the additional quantities and mix of generating capacity desired will in fact be forthcoming. The nation's investor-owned utilities (providing over 90 percent of generating capacity) are not likely to be able to raise the required amounts of capital. Increases in construction costs, fuel costs, and interest charges have recently outstripped revenue growth, and expectations that this trend will continue have made utility investments unattractive. The suspicion is that regulatory procedures have recently caused price increases to lag behind cost increases, resulting in earned rates of return below the cost of capital. If this continues, capacity to meet increased demands—and Project Independence, in whatever form—will not be achieved.

The purpose of this paper is to assess the financial prospects of the nation's electric utility industry, given existing regulatory institutions and continued high rates of growth of demand in the late 1970's. Shortages from regulation would indeed be a turn of events. Economists' analyses of regulatory effects in the 1960's deplored the behavior of commissions on the grounds that they did nothing to control prices (see G. J. Stigler and C. Friedland and R. Jackson). However, the turn of events would not be entirely surprising; using the behavioral approach in analyzing regulation leads one to suspect that commissions operate relatively independent of economic conditions (see Joskow, 1972). The well-established operating rules of the bureaucracies change only when the results of such procedures under inflation or depression become intolerable (see Joskow, 1974). What may have been ineffective regulation in the 1960's may be overzealous regulation for the late 1970's.

I. State Regulation of Electric Utility Prices

Retail prices for electricity, in keeping with long-established mandates from most state legislatures, are regulated by state public utility commissions. The commissions are supposed to monitor the financial performance of firms under their jurisdiction, increasing or decreasing prices so as to allow a return on capital that is "fair." In practice, state commissions appear to be much more passive than this, conducting formal reviews only when firms themselves seek to increase prices. Other procedures, including Dear John letters or jawboning, are used to reduce prices when rates of return rise above what was allowed in the formal case. But the process itself indicates more commission resistance to price increases than initiatives for significant price decreases (see Joskow, 1974).

---

* Assistant professor of economics and Henry R. Luce Professor of Public Policy, Massachusetts Institute of Technology, respectively.

The price increase review process, when initiated, has been highly formalized to center on historical accounting data. First, a test year is chosen for analysis of accounting costs and revenues at existing prices. Operating costs, depreciation, interest charges, and general and Federal taxes (minus any tax credits), plus the allowed profit, are calculated for test-year production. The total of these amounts sets the limit on total earnings. The critical calculations are of the allowed profits—equal to the allowed rate of return times the rate base (the value of capital equipment used in the production of the good or service under regulation). The whole procedure is essentially backward looking; the earned rate of return in the test year is compared with the allowed rate of return, and prices are adjusted upwards or downwards to the point where the rate of return which would have been earned during the test year equals that allowed. Projections or use of future test years have not been used extensively and are now only being considered by regulatory commissions in a few states.

The procedures take a great deal of time. A formal rate case for one of the larger utilities requires first the administrative law judges and then the commissions to examine *ex parte* materials and collections of testimony on all aspects of costs, profits, and prices. This may take from ten months to one year. By allowing temporary rate increases, this processing lag may not affect price immediately, but given that the commissions then are not pressed by waiting companies, a final decision is sometimes made based on data that is over two years old.

The commissions not only take time, but they follow rather simple rules of thumb that do not often require much of the information collected over the review period. In a study of the New York Public Service Commission, it has been found that, on the critical determination of the rate of return, what the commission allows depends upon (a) capital costs, (b) the size of the requested increase in total revenues, and (c) the presence of objecting intervenors (see Joskow, 1972). The last two determinants involve large elements of judgment and bulk large in the results since the commission did not use an economic concept of the cost of capital to set limits on allowed rates of return. Capital costs have more likely been defined as average historical rates of return of other utilities. As these costs held constant or fell, regulation eased; but as they increased under inflation, the invoking of old rules led to more restrictive regulation. The New York Commission in the last few years has judgmentally allowed a larger percentage of requested revenues, specifically in response to inflation. Otherwise, judgments center on extrapolating past judgments (see Joskow, 1972, pp. 643–44). The question is whether this New York response to inflation has been picked up by other commissions and has been sufficiently flexible to keep the rate of return above the cost of capital.

The procedure itself does not warrant optimism. With sharply increasing construction costs and doubling of interest rates, future costs and historical test-year costs bear no relationship to each other.

Revenue erosion can well result where earned rates of return will fall below allowed rates of return (and perhaps below the costs of capital). There are additional sources of flexibility, however. One way of circumventing the established decision rules is through the use of automatic adjustment mechanisms that allow prices to increase or decrease as certain incurred costs change without resorting to a formal regulatory review. Such a mechanism has been widely adopted for fuel costs as a portion of operating expenses: as fuel prices increase, electricity rates are allowed to increase by the same amount on a per kilowatt basis. Thus the regulatory process essentially sets an adjustment formula which then operates automatically as that cost component changes.[1]

Such flexibility, whatever the benefits, has been purchased at potentially high economic costs. The automatic passthrough of fuel charges, along with the slower and more cumbersome regulatory review of other costs, can lead to distortions. The choice of generating techniques may therefore be biased towards energy-intensive turbines away from capital-intensive nuclear capacity. This is to assert the existence of a negative Averch-Johnson effect when waiting costs and rates of return below marginal costs of capital from regulation are entered into the decision-making processes of electric power firms.

II. Costs, Prices, and Financial Performance, 1964–74

Given this regulatory structure, it is instructive to look at costs, prices, and the financial performance of the investor-owned electric utilities in the United States during the past ten years. From 1964 until 1968, operating expenses were essentially constant at about sixty-five cents per kilowatt hour, but thereafter began to rise rapidly and had reached a level of ninety-six cents per kilowatt hour in 1973. At the same time, prices fell during a good part of the decade. From 1964 to 1969, average price per kilowatt hour fell slightly, but beginning in 1970 has risen steadily with the largest one-year increase occurring in 1974 (primarily as a result of increased fuel prices triggering fuel adjustment clauses in most states). The rise in prices came about as a result of increases in the number of formal regulatory reviews from an average of four per year during 1964–68 to fifty-three in 1972 and fifty-six in 1973.

The financial condition of the industry was not greatly improved by the price increases. Interest charges, depreciation, and profits account for the margin between revenues and operating costs. Interest charges, which in 1964 were 4.5 percent on new public utility debt, had risen by 1970 to the level of 8.8 percent. With less stringent monetary policy in 1971 and 1972, the rates decreased, but they have risen since then to 9.7 percent in June 1974. Given such increases, profit rates have declined. The rate of return on equity peaked in 1967 at 12.8 percent and has fallen every year since then (except one) to 11.2 percent in 1973 and 10.9 percent for the first nine months of 1974.[2] Thus the difference between the rate of return on equity and the yield on new long-term debt, which was nearly eight percentage points in 1964, fell to a little more than one percentage point in 1974.[3]

---

[1] Without the added flexibility of automatic fuel adjustment, a number of utilities, especially in the Northeast and middle Atlantic regions, would have been faced with liquidity crises in the face of fuel oil price changes during the winter of 1973–74. But such clauses are being challenged in the courts in a number of states and they may not survive as part of the regulatory process throughout the 1970's.

[2] It should also be noted that in real terms (adjusted by the consumer price index) earnings per share began to fall in 1967 and by June 1974 were below what they had been in 1964. Finally, the interest coverage level for the industry fell continuously over the period to a value of 2.1 by September 1974, extremely close to the limit in many mortgage bond indentures.

[3] The quality of these earnings has also been subject to some doubt. Allowances for "construction work in progress," a noncash item, have recently appeared as a

This financial performance has led to investor expectations that future profits will yield returns below the cost of capital. Stockholders have indicated that they believe this to be the case: by June 1974, average electric utility stock prices had fallen to about 75 percent of book value. External financing is difficult to achieve under these conditions—falling earnings and high interest charges soon put the firm up against legal limits on issuing new debt, and a continued policy of selling stocks at high yields but substantially below book value reduces earnings per share at a multiplicative rate. Thus there may well be limits on the ability to raise enough capital to expand generating capacity.

III. Future Performance under Various Regulatory Regimes

This discouraging outlook could be changed by the behavior of the commissions. The state agencies learned to adjust to rising costs in the late 1960's, at least to the extent that they did not so closely regulate prices that new capacity was difficult to finance. If the commissions allow new inflation premiums, they could in effect provide profits sufficient to raise enough capital to expand capacity at the old rate. Given much higher construction outlay and much greater capital costs for interest and equity financing, these premiums could be spectacular in size.

An initial investigation of the question of premiums is undertaken here through a small-scale experimental financial model of an electric power company. The model is designed to provide some insight into the implications of various regulatory policies under various states of the economy. It does not forecast what the commissions are going to do, but rather restricts discussion to the implications of alternative commission approaches to inflation and rapid capacity expansion. A flow chart of the model appears in Figure 1.

In the model, total revenue is calculated by multiplying the price by the number of kwhs sold for each consuming sector (residential, commercial, and industrial). Each expense item is calculated in detail in accordance with the accounting procedures generally used by regulatory commissions. New investment requirements are met by the use of retained earnings and external financing via long-term debt, preferred stock, and common equity. The company can sell long-term bonds at a specified interest rate as long as its debt ratio is less than 70 percent and its interest coverage is greater than 1.65. It can sell new equity and preferred stock as long as it has earnings after the payment of dividends to existing stockholders sufficient to pay equivalent dividends to new stockholders. If earnings are insufficient to allow for the sale of new debt, or preferred stock, and/or equity (which in total equal external financing) then the State Power Authority is required to provide the additional assets at a specified interest rate. This residual claim represents the capital shortage that the utility faces, and it seems realistic to have it made up by a state entity as investments that have to be made to prevent power outage. The figure therefore gives a measure of potential capacity shortages that might result under different regulatory regimes.

Choosing a sample of twelve of the larger flow-through electric power companies, we use the model to examine four regulatory scenarios. In each case we examine the earnings per share, rate of return on equity, and the ability of the firms to

---

source of earnings of increasing importance. In 1964 this item accounted for only 5 percent of total earnings, but by 1974 it had increased to almost 35 percent of reported earnings. Since this is not a current cash source of income, but rather a credit which will eventually be capitalized in the rate base (when the construction is completed), the earnings figures do not give a good indication of the utility's actual cash flow position. Thus earnings per share and, in some cases, dividends have exceeded cash flow per share by significant amounts.

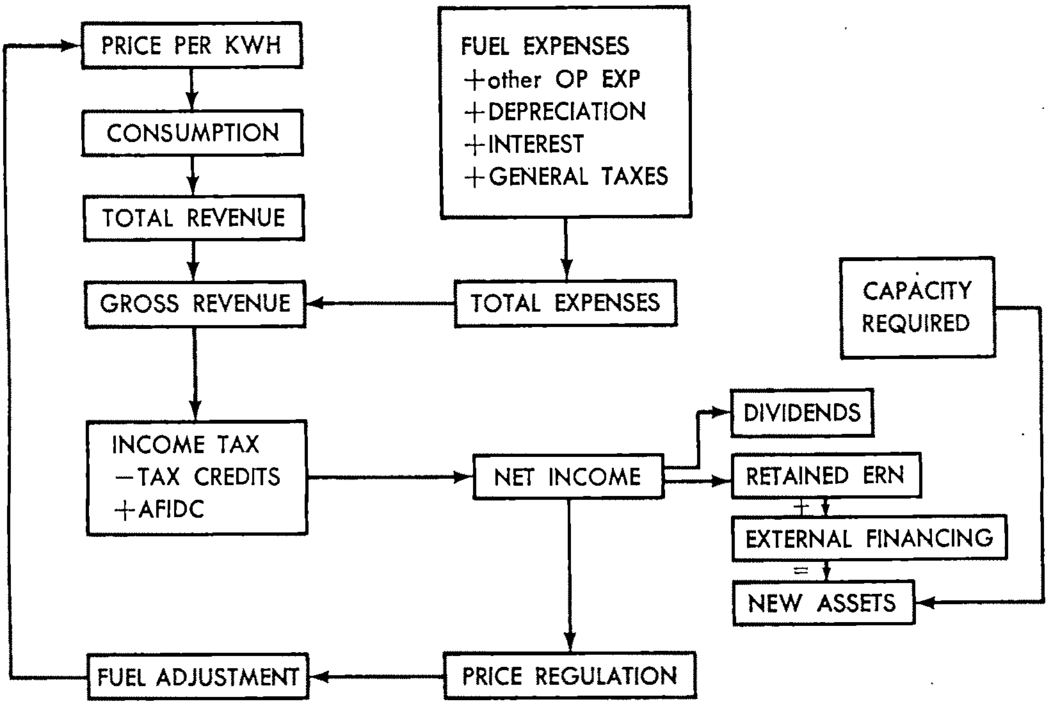

FIGURE 1: FLOW CHART FOR ELECTRIC UTILITY FINANCIAL MODEL

raise the required amounts of capital using retained earnings and external financing for the period 1975–80. Each scenario assumes that Project Independence is a reality, so that capacity has to at least continue to grow at the 1969–72 trend rate. All consumption is assumed to grow at two-thirds of the 1969–72 trend rate. Fuel price changes are assumed to pass through at 100 percent and it is assumed that all 1974 fuel price increases are maintained and increase at a 6 percent rate during the period.

Case 1: Rate of return on equity target of 10 percent used in regulatory hearing plus complete fuel adjustment. Price adjustments are based on historical test-year data (latest twelve months).

Case 2: Same as Case 1 except target is 12 percent on equity.

Case 3: Same as Case 2 except target is 14 percent on equity.

Case 4: Same as Case 3 except target is 16 percent on equity.

In each case we assume that long-term interest rates and preferred stock yields remain high at 10 percent. If equity can be sold, it is at the mean 1973 price/earnings ratio for each company.

Table 1 reports the results for Case 2. Ten of the twelve companies face serious financial problems under these conditions. The capital shortage figures show that these companies will have to either defer some capital acquisitions or rely on state subsidies to obtain the needed capital.[4]

---

[4] To the extent that companies merely defer further expansion, the actual earnings figures reported by the companies will be higher than those projected by the model (because of the absence of the State Power Authority). This may be especially true for the 1974 predictions since one year's needed growth can easily be deferred without serious consequences. In the long run, however, these higher earnings are achieved at the expense of reduced system reliability and perhaps actual shortages by the early 1980's.

TABLE 1—FORECAST EARNINGS PER SHARE, RATE OF RETURN ON EQUITY, AND CAPITAL SHORTAGES WITH A TARGET RETURN OF 12 PERCENT ON EQUITY

Company	Earnings per Share			Rate of Return on Equity			Capital Shortage (Annual in $ millions)	
	1973	1974	1980	1973	1974	1980	1974	1980
American Electric Power	2.9	2.1	2.3	12.4	9.9	11.1	463.1	880.8
Cincinnati Gas & Electric	2.3	1.9	2.2	13.5	10.5	12.2	0.0	112.8
Consolidated Edison (N.Y.)	2.3	2.0	2.3	6.7	6.0	7.6	758.0	1,102.4
General Public Utilities	2.3	1.8	2.4	10.7	8.1	10.9	101.6	593.6
N.Y. State Electric & Gas	3.0	3.0	5.0	9.9	9.8	12.3	0.0	0.0
Northeast Utilities	1.4	1.1	1.4	11.7	8.8	11.2	173.0	311.9
Ohio Edison Company	2.4	1.6	1.7	14.9	10.3	11.3	114.2	410.1
Pacific Gas & Electric	3.2	1.9	2.6	10.8	6.8	10.1	0.0	788.6
Public Service Elec. & Gas	2.2	1.2	2.3	9.1	4.4	8.6	594.5	590.1
Southern Calif. Edison	2.7	2.2	4.9	10.0	7.6	11.4	0.0	0.0
Union Electric Company	1.6	1.4	2.0	10.7	8.9	12.3	4.0	106.4
Virginia Electric Power	2.1	1.3	1.7	11.2	6.9	10.3	428.5	778.9

Table 2 presents the projections of the financial model for 1980 for all four cases. In most cases, the earned rate of return on equity is below that allowed. This result emerges because of the use of historical cost, revenue, and balance sheet data to set returns in the regulatory process while these data do not accurately reflect the behavior of these items in the year that the rates are actually in effect. At 10 percent allowed rate of return on equity, only Southern California Edison and New York State Electric and Gas face no capital shortage. They are able to achieve this result at a fairly low rate of return because they are growing slowly and can finance all new construction through the sale of long-term debt and preferred stock plus retained earnings. Most of the other companies exhibit very substantial capital shortages relative to their capital needs at this allowed rate of return.

When we turn to the 16 percent rate of return on equity case, we see that the

[a] ROR = Rate of return on common equity actually earned.

situation has changed dramatically. Nine of the twelve companies exhibit no capital shortages. In addition, while the three remaining companies still exhibit capital shortages at the 16 percent rate of return, they are only a small fraction of those incurred at 10 percent.

IV. Conclusions

Although the financial model used here is experimental and is in an early stage of development, several conclusions emerge which deserve consideration.

1. The allowed rate of return on equity of 10 or 12 percent chosen by some regulatory commissions will lead to severe financial difficulties and associated capacity shortages.
2. Allowed rates of return of at least 14 percent appear to be necessary to generate sufficient profits to attract financing for capacity growth in line with Project Independence.
3. The critical value of the allowed rate of return on equity which will lift a company out of financial difficulties varies from one company to the next, depending on the rate of growth in output, capacity, and operating expenses. These differences arise in part because of the historical cost-based nature of the rate-setting process which itself leads to earned rates of return below those allowed. This revenue erosion effect seems to be a pervasive characteristic of existing regulatory institutions.

All things considered, the maintenance of existing regulatory procedures may lead to financial disaster for the electric utility industry. Without substantial increases in the rates of return on equity allowed by regulatory commissions, or without changes in the historical cost rate-making process itself, it is unlikely that sufficient capital can be raised to achieve historical growth rates in capacity. Since commissions seem reluctant to base rates on equity returns as high as 14 or 16 percent, the answer must lie in more creative use of future test years, automatic adjustment mechanisms, and alternative methods of calculating a company's rate base. These are, however, only short-run measures which treat current symptoms rather than the root causes of the problem. Efforts must be directed towards incorporating considerations of the marginal cost of production in the rate-setting process. Such a procedure would by necessity be forward looking and would allow prices to increase or decrease as the marginal cost of producing changes over time.

Development Economics—A Reassessment of Goals

By IRMA ADELMAN*

The theme of this paper is the need to be more specific on the goals of economic development and the interdependence between values and goals. This theme is not original; Gunnar Myrdal has argued for many years the importance of values in determining the orientation of development economics. Implicitly, by concentrating on growth, development economists have assumed that other goals, such as greater equity, need not be considered because they are positively correlated with growth. There has been some discontent with this view, but convincing scientific evidence refuting it has not become available until recently. Given that the relationships among the goals of distribution, welfare, and development are by no means simple, it is clearly necessary to examine the purposes of development and to state explicitly the value premises underlying the basic goals. In this paper I shall first review some recent work which bears on these relationships. I shall then propose a minimum humanistic goal for development and, finally, shall suggest development strategies that may permit achievement of that goal.

I. The Evidence

In this section I shall draw primarily on two recent efforts: my latest book with Cynthia Taft Morris and the results of comparative statics experiments performed with a detailed, instrument-specific, general equilibrium model of the South Korean economy, constructed by Sherman Robinson and me.

A. A Review of the Adelman-Morris Findings

Using 1950–63 cross-section data for forty-three underdeveloped countries, Adelman and Morris studied the relationships between the shares of income accruing to the poorest 60 percent of households on the one hand and various broad aspects of a nation's economic, social, and political performance on the other. We found that for the longest part of the development process—corresponding to the transition from the state of development of sub-Saharan Africa to that of the least developed Latin American countries—the primary impact of economic development on income distribution is, on the average, to decrease both the absolute and the relative incomes of the poor. Not only is there no automatic trickle-down of the benefits of development; on the contrary, the development process leads typically to a trickle-up in favor of the middle classes and the rich. The absolute incomes of the poor begin to rise with development only when the nation moves well into the "intermediate" level of development. Further, even here improvement is not automatic: "the poorest segments of the population typically benefit from economic growth only when the government plays an important economic role and when widespread efforts are made to improve the human resource base . . . " (Adelman-Morris, p. 181).

---

* Professor of economics, University of Maryland. With the usual disclaimer of their responsibility, I am indebted to F. L. Adelman, J. L. Joy, C. Taft Morris, S. Robinson, and P. P. Streeten for their most helpful comments.

These results imply that, for a lengthy portion of the process of economic development, there is a conflict between the growth of overall national income and an increase in the welfare of the poor. Equally important, there is an analogous conflict with respect to policy instruments for systematic intervention.

It follows then that, in the formulation of development planning models and development policy, it is necessary to decide in advance the extent to which increases in the welfare of the poor are to be weighed against simple growth of *GNP*. In addition, traditional economic instruments of policy appear to have only a weak, or at most a nonsystematic, effect on the relative share of income accruing to the poor. Indeed, our study "reinforces the view that the policy instruments that are most effective in improving income distributions are different from those that are best for raising economic growth rates" (p. 185). It also supports the view that "economic structure, not level or rate of economic growth, is the basic determinant of patterns of income distribution" (p. 186).

Implicit in these conclusions is the suggestion that the price of economic equity is high: a necessary condition for its achievement is radical structural change.

B. *The Adelman-Robinson Model*

In order to test the validity of this last hypothesis, an income distribution-oriented planning model of an ambitious and novel variety was formulated.[1] The results of comparative statics experiments with the model reinforce the conclusions of the Adelman-Morris book. Dynamic experiments are now in process.

The model is designed to investigate the impact of a variety of traditional economic instruments on income distribution: relative factor prices, product prices (influenced directly through price fixing, taxes, subsidies, and/or world prices, and degree of monopoly), rationing of products and services, rationing of credit, government taxes and transfers, trade policy, labor market policy, technology, and inflation. The model is dynamic and instrument-specific. It captures the effect of various policy instruments on distribution through a modified general equilibrium approach in which both factor prices and product prices are endogenous. Given the initial ownership of assets and the institutional rules of the game, the short-run income distribution derives from the interaction of production and consumption decisions.

The model is capable of portraying a large variety of economic and institutional rules of the game. One can vary the degree of monopoly, the principles of operation of credit markets, the clearing principles for labor markets and for commodity markets, and the permissible degrees of disequilibrium in individual markets. The model combines Keynesian and Walrasian analysis (it can operate in either mode, depending on the labor market specification). It portrays a monetary economy (combining Schumpeter-Wicksell with Walras) open to foreign trade. It can be run in an equilibrium or in a disequilibrium mode. The model is rich in sectoral detail (twenty-nine sectors), is disaggregated by firm size (four per sector), and has fifteen factors of production and twelve socioeconomic consumer (= saver) household categories.

Solution for each time step is by tatonnement in a two-stage process. In the first stage an allocation of investible funds is made across sectors and firm sizes by making firm demand (based on production functions and anticipated sales, rates of return, and capital cost) consistent with a given interest rate, a target credit expansion, or a direct rationing program. The second stage of the model is a microeconomic market model rich in institutional, sectoral, firm size, and household category detail. A series of markets must clear—a process that determines production, employment, prices, wages, and income distribution. Before the next period the model updates the variables, sets expectations, and selects credit and trade regimes for the first stage of the next period.

---

[1] Work on this model has been supported by the International Bank for Reconstruction and Development.

This model has been implemented for South Korea. Some indication of the validity of the model may be inferred from the fact that the base period solution for the model reproduces the 1968 data to within less than 1 percent for every one of the approximately 2,000 endogenous variables.

Some of the comparative statics experiments performed to date are listed in Table 1. The results of these experiments are summarized in Tables 2 and 3. Each column of Table 2 indicates the distribution of household income after the model is solved under the conditions of the corresponding experiment, indicated at the top of the column. There appears to be a remarkable insensitivity of relative income distribution to the experiments performed. Table 3 indicates the composition by socioeconomic group of the lowest decile for each of the experiments. The bottom row of the table gives the average real household income of the decile. An examination of this table suggests, by contrast, that economic policy, by changing the functional distribution of income, can play a major role in determining who are the poor

TABLE 1—DESCRIPTION OF COMPARATIVE STATICS EXPERIMENTS
Adelman-Robinson Model

Experiment	
A–1	Peg agricultural prices at 1.25 of base price.
A–2	Increase agricultural capital stock by 50 percent.
A–3	Increase agricultural productivity 25 percent in cereals and 15 percent in other agriculture. Peg both prices at .90 of base price, and allow free trade in agricultural products.
A–4	Increase productivity in cereals by 25 percent and give cereals a price subsidy of 25 percent.
B–1	Double all direct taxes on households and transfer the proceeds to skilled labor, apprentices, and workers.
B–2	Give price subsidy of 20 percent to labor intensive sectors. Increase their capital stock by 20 percent. Peg their prices to world prices, allowing unlimited exports.
B–3	Same as B–2 but, in addition, increase agricultural productivity by 25 percent.
C–1	Increase entire capital stock by 50 percent.
C–2	Increase capital stocks by 50 percent for nonagricultural firms with less than 50 employees (two smallest sizes).
D–1	Increase all exports by 25 percent.
D–2	Devalue by 30 percent. Peg prices of traded goods to world prices. Increase capital stocks of trading sectors by 20 percent.
E–1	Increase supply of engineers, technicians, skilled workers, and clericals by 10 percent, reducing the number of unskilled workers correspondingly. *CES* functions.
E–2	Increase elasticity of substitution between capital and labor in manufacturing.
E–3	Set minimum wage at 125 percent of unskilled wage rate.

and, in particular, whether they are primarily urban or rural. There is also somewhat more scope for affecting the absolute level of poverty through economic intervention than for changing the overall distribution of incomes.

The remarkable insensitivity of the relative shares of national income accruing to households by deciles to the wide array of economic policy packages represented in the model suggests that, while one can make small gains in the welfare of the poor through large changes within the system, the goal of equity cannot be achieved without radical reform. This result is consistent with the Adelman-Morris findings.

C. A Major Conclusion

The two studies just described attack the issue of income distribution and de-

velopment with two very different techniques and bodies of data. The general conclusions they reach are very similar and therefore strongly reinforcing. Both studies show quite clearly that, in approaching the subject of economic development, whether theoretically or in terms of policy formulation, one cannot duck the issue of the purpose of development. This is a result of extreme importance: very different models, policy instruments, and disciplinary mixes are implicit in the choice of objectives. It is not simply a matter of tradeoffs; the optimal time sequences of dynamic strategies are almost certainly quite sensitive to the choice of goals. The conclusion is inescapable that, in setting the directions for the future of the field of economic development, we must be very clear, much clearer than we have been in the past, in our choice of development goals.

II. Development Objectives

The currently accepted definition of development focuses upon the creation of conditions for self-sustained growth in per capita *GNP* and the requisite modernization of economic, social, and political structures implicit in the achievement of this goal. To the extent that growth in *GNP* and concomitant changes, on the one hand, and improvements in the welfare of the poor, on the other, are monotonically and positively related (except possibly for short-term startup problems), this definition of development could offer an acceptable working definition. If, however, as is suggested by the work described above, a *U*-shaped relation exists, then the accepted definition of the development is, at the very least, badly misleading as a focus for thought and practice in the field. Since trickle-down does not work, basing the definition of the process of economic development upon a faulty analogy with modern industrial nations has led to the use of incorrect performance criteria, the selection of largely incorrect development strategies, and the use of inappropriately framed models and inappropriately focused planning methodologies.

On a moral basis, it seems to me that in each nation the proper long-term goal of national development policy must be the successive relaxation of the systemic obstacles to the full realization of the human potential of its members. The goals of *economic* development are then twofold: to provide the material basis for achieving these objectives and to establish the economic conditions for relaxing the other barriers to self-realization (access to education, work satisfaction, status, security, self-expression, and power). The proper balance between these two economic goals is a dynamic one and will depend on the state of welfare of the poorest segments of the population at each decision point.

This definition of the purpose of development, which I shall call ***depauperization***, is humanistic, largely spiritual, and highly dynamic. It is focused upon individual welfare, as perceived by the individual himself, with full recognition of the nonmaterial, human relations, and intergenerational aspects of personal welfare.

Depauperization has both economic and noneconomic dimensions and stresses the removal not only of material but equally importantly of social, political, and spiritual forms of deprivation. It involves not only equity but more significantly the creation of conditions conducive to continuing improvements in equity. It may require temporary sacrifices in national economic growth and involves major social, political and institutional change. In addition, the optimization of some of the components of this overall objective may, in the short run, necessitate sacrifices in some of the others, so that the ultimate realization of depauperization is likely to require appropriately phased sequences of dynamic strategies, each aimed at optimizing some subset of the total goal package.

In order to develop appropriate criteria, strategies, models, and methodologies for future development decisions, it is important to distinguish among four conceptual goals: equity, growth, equitable growth, and depauperization. Equity, growth, and depauperization are all special cases of equitable growth. Equity lies at one extreme. Equity alone as a goal, with growth given a subsidiary role, implies that the most important objectives are justice and fairness in some sense, rather than absolute welfare. Growth alone as a goal lies at the opposite extreme and has been discredited, as indicated above, in the minds of most of us. Depauperization, like equitable growth, involves some weighted combination of equity and growth, but in view of its explicit emphasis on the dynamic and nonmaterial aspects of individual welfare, depauperization lies well towards the side of equity. It implies that a primary objective of development is not only to help the poor to achieve a decent standard of living but in addition to create the conditions, economic and otherwise, that will allow them and their children continuing equal access to opportunities for self-realization. The achievement of depauperization, therefore, requires institutional change, a measure of economic, social, and political equity, and economic growth, not as goals in themselves but as instruments for the achievement of permanent self-perpetuating gains in the welfare of the poor.

A normative judgment implicit in depauperization is that no societal process can be morally acceptable which imposes, maintains, or intensifies the objective and perceptual barriers to self-realization of major segments of that society. To my mind, the major crime of humanity—practiced on an appalling scale—is to create and enforce, by means of institutional barriers and structural dynamics, conditions which lead to the waste of as much as 90 percent of its potential for fulfilled life, creativity, and personal growth. Empirical evidence shows that the natural historical process of modern economic growth works systematically to perpetuate those conditions for most of the period from the beginning of economic modernization. To counteract this social distortion should be a basic purpose of all national social policy and a prime objective of international assistance; to show how this might be done should be a major objective of all social scientists concerned with development.

III. Strategies for Depauperization

Most of the discussion concerning development strategies has been in terms of contemporary tradeoffs among major policy packages, rather than in terms of sequences of more or less pure strategies. A cursory survey of the dynamic processes that have led to the development of the currently industrialized nations suggests, however, that the development process has in fact proceeded as a sequence of pure strategies, rather than in a progression of mutually balanced strategy mixes. Emphasis on strategies that focus on a single major objective (such as the creation of a viable political system, or industrialization, or social development), largely unaccompanied by concomitant changes in the rest of the system, has in general created strategic imbalances which set conditions for the next phase. It is only at the beginning and the end of the entire process that there appears to be a balance among the various features of economic, social, and political development.

An examination of the development process of those non-Communist countries which have recently successfully combined improvements in the incomes of the poor with accelerated growth (Israel, Japan, South Korea, Singapore, and Taiwan) shows that they all have followed a similar dynamic sequence of strategies, varying only in the extent and consciousness with which it has been pursued. Aided by large infusions of foreign capital, all of these have followed the following dynamic sequence:

Stage I: Radical asset redistribution, focusing primarily on land;[2] but also imposing (at the very minimum) curbs upon the use and further accumulation of financial capital. This stage may involve negative growth rates, but is necessary to set the economic and political conditions to ensure that subsequent economic growth is not highly unequalizing.

Stage II: Massive accumulation of human capital, far in excess of current demand for skills. In this stage ownership of human capital is redistributed, the human resource base is vastly enlarged, and both the economic opportunities and the political pressures for the next stage are generated. In all five countries, this stage was accompanied by relatively slow rates of economic growth and, at later times, by political instability, social tension, and unrest.

Stage III: Rapid, human-resource-intensive growth. After the investment in human resources has been made, continuing depauperization requires that subsequent increases in growth rate be achieved through strategies that stress rapid labor-intensive growth. This implies that sufficient attention must be paid to the formulation of economic policy. In the smaller nations development will have to be oriented towards export markets. In large countries, on the other hand, industrialization can be oriented more towards satisfying domestic demand, particularly when a more equitable growth pattern generates a mass consumer market and when a more appropriate import-substitution technology is found.

To achieve depauperization, two extreme strategies are theoretically possible: grow now, redistribute and educate later; or redistribute and educate now, grow later.[3] The former strategy is the one that has typically been followed historically in developed non-Communist economies, except for the United States and Japan. The redistribute-first strategy is the one followed by the successful equitable-growth countries in the past two decades.

I am convinced that for rapid depauperization there must be a deliberate application of the redistribute-and-educate-first strategy on a wide scale. My argument is a practical one: there is selective but consistent evidence that this strategy can work and significant evidence that the opposite strategy does not work on anything resembling an acceptable time scale. Once the slower growth phase of Stages I and II is passed, the transition to a stage of relatively high development can be accomplished in short order. In the five countries considered, the first phase lasted about a decade. In another decade and a half, once economic incentives were restructured to permit an export-oriented industrialization that employed the new skills of the population, both depauperization and rapid economic growth became self-sustaining.

Some may dismiss the success stories as special cases, asserting that these are all small nations with nonrepresentative cultural traditions and attitudes, helped by unusually large per capita infusions of foreign aid and subjected to exceptional challenges that strengthened the legitimacy of their governments and made economic viability a major condition for national survival. Special cases they may be, but five successful cases are certainly more encouraging than none, and the consistency of their experiences surely weakens the "uniqueness" argument.

---

[2] Except in Singapore, which is entirely urban. A major welfare program, however, accomplished some of the same redistributive objectives.

[3] The remainder of this section is a minor reediting of Adelman (1974). While originally written as a prescription for equitable growth, I have since recognized that the prescription is more precisely one for depauperization. The recommendations for achieving a weaker form of equitable growth would differ primarily in the relative emphasis on growth and equity and the relative emphasis on social, political, and institutional changes compared with purely economic actions. The specific policies associated with achieving the respective goals would differ considerably more than the goals themselves.

There is also evidence that the entire package—resource redistribution, massive education, and labor-intensive growth policies—must be adopted in that sequence to achieve rapid success. Incomplete versions of this program, such as land reform alone or education without labor-intensive growth, have not worked. For the advanced countries which followed a grow-first pattern, economic development did eventually benefit the poor, but the time it took to do so was much longer (roughly two or more generations) than in our five successful cases.

The traditional strategy for economic development—rapid economic modernization involving trade and investment policies aimed at the fast expansion of the industrial sector—has not been so much wrong as premature for most developing countries. When applied *at the proper time in the proper strategic sequence* (i.e., *after* the equalizing preconditions of Stage I and Stage II), labor-intensive rapid industrialization phased in with appropriately paced agricultural development appears to be the key to realizing the full economic value of the redistributed assets and, hence, to *actual* depauperization, rather than to merely potential depauperization, as in Stages I and II.

The Structuralist Approach to Development Policy

By HOLLIS B. CHENERY*

Several approaches to the analysis of developing economies have evolved over the past twenty-five years. From a methodological standpoint, they can be grouped under three main headings: neoclassical, neo-Marxist, and structuralist. The first two attempt to adapt systems of thought that were initially formulated for the study of industrial societies to the less developed countries. The structuralist approach attempts to identify specific rigidities, lags, and other characteristics of the structure of developing economies that affect economic adjustments and the choice of development policy.

The initial set of structural hypotheses was formulated in the 1950's by writers such as Paul Rosenstein-Rodan, Ragnar Nurkse, W. Arthur Lewis, Paul Prebisch, Hans Singer, and Gunnar Myrdal. They explain phenomena such as balance of payments disequilibrium, unemployment, and worsening income distribution on the basis of particular properties of demand and production functions and other specifications of economic behavior. A common theme in most of this work is the failure of the equilibrating mechanisms of the price system to produce steady growth or a desirable distribution of income.

The success of a number of developing countries in accelerating their rates of growth in the 1960's casts some doubt on the significance of the structural problems that had been identified in the previous decade. However, in the past few years the importance of structural rigidities has been reemphasized by several new phenomena: the limited ability of economies to absorb the growing labor force, the worsening of the income distribution in several developing countries, and—most recently—the disruption to world trade caused by increased oil and food prices, which will require a substantial adjustment in productive structures. In short, development policy again seems to be constrained by a number of structural factors that require a more explicit analysis of the possibilities for short-term adjustment and for longer term changes in the economic structure itself.

In this brief survey, I will try to present an overview of structuralist methodology and to compare some of its policy conclusions to those of the other main approaches. Since there is not yet a unified theoretical framework for structural analysis, I will select formulations that seem to provide a promising basis for future research.

I. Methodology

The methodology of structural analysis has evolved over the past twenty-five years from a set of rather intuitive hypotheses to models of increasing empirical validity and analytical rigor. This evolution can be summarized in three stages: formulation of hypotheses, empirical testing, and the elaboration of more complete models. This sequence can be illustrated for two of the basic elements of structuralist systems: the concept of a dual economy and the concept of complementarity in demand, which underlies theories of balanced growth.

---

[*] Vice President for Development Policy, World Bank. I am indebted to Bela Balassa, Helen Hughes, Graham Pyatt, and Wouter Tims for helpful comments.

The concept of a dual economy stems from the observation that development takes place unevenly both within and between sectors of an economy. Although this concept has had many different formulations, the most influential is that of Lewis. He makes three basic assumptions as to the structure of a developing economy: (1) that technology can be divided between capital-using (capitalist) and noncapital-using (subsistence); (2) that the labor supply is elastic at a conventional wage; and (3) that saving is done largely by the recipients of nonwage income (capitalists). These assumptions, or variants of them, have been incorporated in models that explain the acceleration of growth, the allocation of the labor force, and changes in the distribution of income.

The early formulations of concepts of balanced growth by Nurkse and Rosenstein-Rodan also relied on a simple set of structural hypotheses: (1) a generalized version of Engels' law, specifying that consumer demand for food, clothing, shelter, and other major commodity groups is mainly a function of income and little affected by relative prices; (2) a similar assumption as to the limited price elasticity of demand for exports; and (3) in Rosenstein-Rodan's formulation, the importance of economies of scale in overhead facilities and basic industries. The first two assumptions make it necessary to expand output and allocate investment in close relation to the pattern of domestic demand. They also provide an explanation for structural disequilibrium and slow growth in countries that fail to do so.

Both sets of assumptions have in general stood up well to subsequent empirical tests. The acceleration of population growth has probably made the surplus labor assumption more generally valid today than when it was initially formulated for underdeveloped countries. Econometric tests by R. Weisskoff and C. Lluch and A. Powell provide some support for the generalized version of Engels' law underlying the theory of balanced growth, since they show most price elasticities to be less than unity. Among the basic structuralist assumptions listed, only the assumed inelastic demand for exports needs to be seriously qualified.

The third stage of theoretical refinement and policy application has proved more difficult. In the first place, it has been shown that the structural relations posited are not sufficient to lead to some of the policy conclusions suggested in the original formulations. As in the case of the Keynesian assumptions, a more complete formulation of models that can be statistically estimated has proved necessary in order to reach useful policy conclusions. Much current work consists in developing a second generation of models in the structuralist tradition that are designed for statistical application in individual countries, rather than for deriving broad generalizations.

The structuralist approach has had a substantial impact on both internal and external development policies. In both instances it focuses on identifying the consequences of various kinds of structural disequilibria. In domestic policy, the principal phenomena examined have been the effects of surplus labor on resource allocation and more recently the interpretation of worsening income distribution as resulting from a set of disequilibrium conditions. In international policy, analysis has focused on the nature of structural disequilibrium in the balance of payments and its effect on trade and aid policies. The following sections examine some of the relationships between the methodology employed and the policy conclusions reached in these two areas.

II. Internal Development Policy

Unlike the neoclassical assumptions, the structuralist alternatives do not lead automatically to policy conclusions. To produce such conclusions, they must also be embodied in an explicit general equilibrium framework. For this purpose, most analysts have used one of two simple models: either a neoclassical model with particular structural relations added or some version of a linear Leontief input-output model, which excludes most forms of substitution. The neoclassical framework minimizes the effects of the specific rigidities in the economic system, while the input-output system tends to exaggerate them.

Most elaborations of the dual economy and surplus labor concepts have been made in a two-sector neoclassical system, as in the work of J. C. Fei and G. Ranis, L. Lefeber, and A. C. Kelley, J. G. Williamson and R. J. Cheetham. One policy result from this type of model is to determine the shadow price of labor, which can then be used in project evaluation and in establishing the need for labor subsidies. Empirical applications of these models have been limited by the lack of data on different aspects of dualism. It will require some expansion of the two-sector framework before statistical estimation of the underlying structural relations becomes feasible.

The balanced growth hypotheses have been widely used in empirical analysis and are usually incorporated in input-output models which include foreign trade. These are applied to the formulation and testing of development plans, as illustrated in surveys by Chenery (1971) and A. Manne. Apart from its use in country planning, this type of model can also be used to deduce more general propositions through systematically varying the structural parameters and determining a set of solutions based on either simulation or optimization.

This form of sensitivity analysis lends considerable support to some of the conclusions of balanced growth theorists. For example, it is necessary in larger countries to expand agriculture at a rate that is largely determined by the income elasticity of domestic demand for foodstuffs because of the limited possibilities of expanding nonagricultural exports to offset a shortfall. Failure to meet this condition has retarded growth in a number of countries. This conclusion does not apply when industry is disaggregated to individual sectors such as steel or fertilizer, however, in which the optimal investment allocation to sectors having economies of scale is characterized by the alternating pattern of expansion of production and imports described by T. Scitovsky and by Chenery and L. Westphal.

The elaboration of structuralist hypotheses in planning models has also focused attention on the value of flexibility in adapting resource allocation to changing circumstances. This problem does not arise in the neoclassical system, which assumes perfect foresight and a high degree of substitutability. When these assumptions are abandoned, flexibility can be provided by increased exports or capital inflows and by planning some excess capacity in physical and human capital stocks. Although a formal treatment of the benefits of flexibility and the ways of achieving it has not been developed, this is an important problem for developing countries which cannot be analysed in the neoclassical system.

The revival of interest in income distribution has added a new dimension to structural analysis. The traditional approach focuses on the division between wage and nonwage income and is ill suited to developing countries, in which modern sector wage earners are in the middle-income groups. Recent studies by M. S. Ahluwalia have brought out the fact that the bulk of the poorest groups in developing countries are self-employed and largely rural. Their incomes depend more on the availability of land and capital and access to public facilities than on wages. Since each of the main poverty groups—small farmers, landless laborers, urban self-employed—has a different set of productive possibilities and constraints, a new form of structural analysis based on identification of these groups is necessary for distribution-oriented policies.

This recognition of the importance of asset distribution does not necessarily lead to the Marxist conclusion that the redistribution of existing assets is the only alternative. Measures to redistribute increments in income and new asset formation are more likely to be acceptable to the majority of the population and less disruptive of development in most countries. Development strategies based on this approach are elaborated by Ahluwalia and Chenery. The neo-Marxist policy recommendations suffer from the same defects as the neoclassical in that they are implicit in the initial assumptions rather than being derived from an analysis based on empirical estimates of the underlying structural relations.

III. External Policy

The conflict among the three analytical approaches is perhaps most acute in the area of external policy. The neoclassical approach tends to exaggerate the benefits of trade in an open economy when it does not explicitly consider the effects of uncertain export prices and the difficulties of shifting resources to meet changing market conditions. Conversely, the neo-Marxist approach exaggerates the costs of "dependence" on external trade and investment and tends to ignore the benefits of the technological transfers that accompany them. The early structuralist views have also proved to be excessively pessimistic as to the possibilities and benefits of nontraditional exports of manufactures and services.

The structuralist concept of development as characterized by rigidities that limit economic adjustments requires an analytical framework in which external policy is more closely linked to domestic resource allocation than does the neoclassical view, which minimizes these restrictions. Attempts to formalize these relationships started from simple two-gap models, which incorporate explicit limits on the rate of increase of domestic saving, investment, and exports. These models were elaborated by including optimizing procedures and shadow prices, the disaggregation of productive sectors, and more explicit treatment of structural change over time, as in the work of Chenery and A. MacEwan, M. Bruno, and S. D. Tendulkar. Experiments with these types of models in a number of countries have led to several general conclusions as to development analysis and policy, the most significant of which are: (1) the enhanced value of increased exports and capital inflows in bottleneck situations, in which the trade limitation is more restrictive than supplies of capital and skilled labor; (2) a restatement of the empirical basis for assessing comparative advantage over time in relation to the factors limiting development; and (3) clarification of the relation between internal and external constraints in the evaluation of individual investment projects.

During the 1960's a number of countries progressed from an initial strategy of import substitution to the promotion of manufactured exports after they had developed a sufficient industrial base to do so. As countries achieve a more diversified productive structure and reduce their concentration on a few exports, the difference between the neoclassical and structural prescriptions diminishes because some of the constraints that had previously limited growth are no longer significant. An assessment of the experience of some of the industrializing countries that have made this transition—Taiwan, Israel, Korea, Brazil, Mexico—suggests that earlier conclusions as to the high cost of the initial stage of import substitution need to be reexamined in light of the subsequent ability of the country to shift to manufactured exports and break out of the phase of trade limited development. This evaluation suggests that the dichotomy between inward-oriented and outward-oriented policies has perhaps been overdrawn, and that these policies can be more usefully viewed as sequential elements of a strategy designed to bring about changes in the structure of both production and trade.

The basic issues of the relations between trade and growth have been reopened in a new form by the substantial changes in relative prices that have taken place over the past two or three years. The main beneficiaries have been the oil-producing countries, which now have a structural problem of unprecedented magnitude in increasing their capacity to utilize their greatly increased export revenues. Most of the rest of the world has the opposite problem of adjusting its economic structure—through import substitution, increased exports, and redirecting trade—so as to accommodate a substantial worsening in its terms of trade. Not only has world income distribution been made worse by the present and prospective reduction in growth of the poorest countries, but within these countries the policies to improve income distribution are also being weakened. For most developing countries, increased import prices mean a return to a condition of a dominant trade gap and large capital inflows for the next few years. They need to give highest priority to reallocating resources so as to expand exports and gradually reduce capital inflows over a reasonable period.

This shock to the system of world trade has emphasized the advantages of the more flexible economies, such as Taiwan, Korea, and Brazil, which appear to be able to absorb large increases in import costs through a combination of increased exports and borrowing, while still maintaining substantial rates of growth. Conversely, the countries most severely affected by the rise in oil and food prices are those which are dependent on primary exports, whose prices kept up with world inflation for only a brief period, and which do not have the flexibility to shift readily to other exports. Unless oil prices are drastically reduced (which seems unlikely), substantial increases in capital flows to these countries will be needed over the next few years if they are to sustain even moderate rates of growth.

IV. Conclusions

The preceding discussion has illustrated the relations between theoretical premises and policy implications in several fields of development. The simplifying assumptions of the models currently in use tend to exaggerate the differences between neoclassical and structuralist prescriptions. As statistically determined relations replace a priori hypotheses, it is predictable that these differences will be reduced. A similar process can be hoped for when neo-Marxist theorists turn their attention to verifying their hypotheses.

Although better knowledge of elasticities of substitution in demand and production would do quite a bit to reduce the conflicts in policy guidance, several real differences in basic concepts remain. Neoclassical policy consists essentially in removing impediments to the functioning of markets so as to make the real world as much like the abstract model as possible. However, it will never be possible to achieve perfect knowledge or instantaneous adjustment to market signals. It is therefore necessary to incorporate these "imperfections" into the model itself. Once this has been done, it will become possible to take account of the existence of internal or external disequilibria and to devise more realistic policies to cope with them. In the theoretical literature, these policies are misleadingly referred to as "second best" in relation to the neoclassical model. It would be more accurate to characterize the model itself as overly simple and "first best" policies as simply unattainable. More attention should be given to improving the realism of basically neoclassical models instead of discarding them in favor of equally oversimplified structuralist formulations.

In minimizing or ignoring the advantages of market adjustments, structuralist (and Marxist) policy prescriptions usually put too much weight on the limited administrative apparatus of developing countries. As A. Hirschman has stressed, this is one of the main limitations to development; it should be allowed for by not seeking too much fine tuning of development policy. Difficulties in implementing a complex set of policies may prove much more costly than the allocative inefficiency of a simpler program that can be more readily carried out.

Finally, it must be recognized that the task of development has been made much more difficult for most countries by the recent changes in the world economy. Virtually every country is currently suffering from more or less serious disequilibria in its economic structure. Despite our desire to give greater weight in development policy to distributional considerations, this cannot be achieved without giving equal priority to adjustments in external trade and capital flows.

State of Development Economics

By Stephen A. Resnick*

The current state of development economics is reflected all too well by that of neoclassical theory—both are in a mess because of the lack of reality of the assumptions upon which they ultimately rest. What we now observe in the field of development is a focus upon reducing market imperfections, especially in the financial and trade sectors, and increasing investment in human resources. Development economists seem to have taken the institutional and historical development data into their academic offices, beaten the theory out of it, and come out with an *ad hoc* policy package of applied micro theory, no more useful in this field than in any other. Yet there has been a continuity to development theory that explains why it tends to be useless in explaining the reality of poverty and inequality and why, despite a passing appreciation of historical phenomena, it is a field that is totally ahistorical. What all of development economics since World War II have in common is the failure to see that the poverty of third world countries was never independent of the relative affluence of center countries. Specifically, the economies of the hinterland have been systematically organized and this organization historically reproduced by political and economic forces within the center to pump out unpaid surplus labor.

This alternative view is in complete contrast to what might be called neoclassical development theory for it analyzes unequal distribution of income as an essential and endogenous part of capitalist development. The major difference between the two approaches, about which there is much confusion, is the use of the concept "capitalism" to modify development and its derivative "imperialism" to analyze the process of international development.

The basic contrast between neoclassical and Marxian development theory must be found in the different underlying theories of value upon which each rests and from which each draws its logical framework and tools of analysis. In the neoclassical view of development, relationships of exchange not only dominate or determine production relationships, but take on a life of their own in explaining changes in a society over time. These exchange relationships depend upon preferences or choices of individuals as revealed in the market and ultimately upon some subjective concept of utility. This is perhaps a strong statement for rarely does one observe the explicit assertion that this is the theory being used. Nonetheless, upon what else is it to be based? Certainly an explanation based upon class analysis or the concept of exploitation would be an anathema to neoclassical development theory. The theory might be based upon some nebulous sociological notions of how primitive societies operate, but few economists would get caught holding this view. Perhaps all that really matters is the planning of development by the manipulation of carefully calculated input/output tables or the pragmatic use of incremental cost/benefit exercises. Even if one makes the heroic assumptions necessary to use the technical coefficients and somehow assumes that these coefficients are independent of government development policies, use of the technical

---

* Professor of economics, University of Massachusetts. I would like to thank Richard Wolff for his helpful comments.

planning approach, no matter how complex the models, must quickly come into conflict with the reality of national and international political relationships. Moreover, once the matrices are inverted, there remains the bothersome theoretical problem of what determines the wage rate of labor and/or the entrepreneur's decision to save and accumulate capital. Sometimes the power of technique lies in its ideological dimension which allows the economist as technician to ignore both the theory upon which it ultimately rests and the political economy that produces that theory.

What we currently observe is a careful analysis of those necessary reforms, taken from neoclassical theory of perfect competition, to allow the smooth workings of supply and demand in all sectors of the economy. The attempt is to resurrect and use the perfectly competitive model to explain not only why twenty-five years of import-substitution industrialization and growth of national output have not succeeded in remedying poverty, but also why, as has been commonly rediscovered once more, the distribution of income and wealth is getting more uneven over time. The view rests on the notion that the state through its financial and fiscal instruments has produced market imperfections that frustrate the development of free markets in both factor inputs and commodity outputs, and this has led to a less than optimal allocation of resources.

A policy package that deals with the more obvious imperfections, such as monetary and credit changes that allow the market rate of interest to reflect the opportunity cost of capital, foreign exchange devaluation and tariff changes and major reductions in quantitative restrictions on foreign trade that produce a more uniform ad valorem tariff structure directed toward reducing overall levels of protection, and tax and expenditure reforms that remove differential incentives to favored groups, will ultimately allow a situation where market signals perform their proper allocative role. Once accomplished, the distribution of income will be determined by the logic of the impersonal market, such that each factor receives what it deserves in terms of its marginal contribution to output.

These changes are seen as gradually moving the economy to its potential production possibility frontier by allowing it to find its Ricardian comparative advantage in the export of labor-intensive manufactures and as facilitating the growth of agricultural output by removing distortions that discriminate against it. Reforms are also seen as releasing a good deal of entrepreneurial talent, especially that bottled-up in the so-called informal urban and rural sectors.

Neoclassical development has moved to this emphasis on the freeing of markets to reflect opportunity costs and consumer preferences from a previous approach that placed more emphasis on institutional change per se, big pushes whether in agriculture or industry, and the breaking of vicious circles. Yet the differences are more apparent than real for both views share the common faith that the developmental effort must be to minimize those barriers to the effective operation of supply and demand, whether caused by cultural factors, indivisibilities, or by government-induced distortions, so as to maximize the individual private enterprise of each agent in the society. Thus, these views are quite consistent with neoclassical theory.

What is wrong with this approach? First, the theoretical argument is invariably confined to the realm of exchange relations. It omits the underlying national or international relations of production out of which emerge a specific institutional environment and a specific set of supply and demand equations. Second, the policies advocated, consistent with the theory, are seen as necessary reforms of distorted internal market relations that will allow the economy to independently break out of the postwar industrialization experience to compete effectively on the international market. However, this very international market serves as the principal vehicle by which units of production in the center exploit those in the hinterland and prevent their independent development.

Simply put, the neoclassical approach is misspecified because of the omission of production relations and thus yields biased policy conclusions and unreliable predictions. Further, although this approach has recently appended to its analysis the more obvious social and political issues, they are added as unexamined external givens never seen as the direct outgrowth of the underlying structure of production, i.e., the value relation between labor and labor power. Neoclassical development cannot analyze anything outside of a framework of market or exchange relationships because that is the theory upon which it is based; it is trapped not by inadequate data or lack of "better" models, but rather by its narrow focus on supply and demand and its total neglect of those historic forces that have produced international relations of production and technology based upon an exploitive system of one class over another.

In contrast, a Marxian approach to development begins with a theory of value based upon relations of production determined historically; it is these relations that determine or govern those of exchange. What we observe in the hinterland are those dependent social relations of production and underdeveloped forces of production produced historically and reproduced currently by international capitalist development. Capitalism develops the hinterland not by underdeveloping it in the sense of making producers independent of markets, but rather by integrating it into the world market. It is the specific role of imperialism to systematically develop, integrate, and coordinate production in the hinterland into a specific pattern of international commodity and capital flows. Historically, imperialism produced a complex network of production and finance that continually operates so as to keep the hinterland dependent on the center. International trade becomes the economic mechanism that links and binds together modes of production in different areas of the world, and the actual or potential use of force is the final political weapon that prevents them from falling apart. Thus it is the capitalist mode of developing the international division of labor that makes commodity production a universal category, thereby creating one capitalist world comprising two unequal but dependent subsections. In this process, the hinterland's needs and tastes are divorced from its own history and its own social development and, along with comparative advantage and prices, are made a function of the center's economic growth and political power.

Relationships between center and hinterland, however, are not static, but must be understood within the changing process of capitalist development. Otherwise what seems to be exogenous to the hinterland is in reality the internal development of international capitalism. Specifically, the quantitative and qualitative changes that have occurred since World War II in the hinterland cannot be understood or analyzed properly independently of the historic process of capital accumulation in the center.

Although imperialism has a long history, the form of exploitation has changed. In the early phases, the merchant capitalist often used coercion directly to pump out surplus labor from peasants. Plunder, looting, and slavery were used in this process of slash and burn capitalism to create those fortunes that helped to finance the primary accumulation of capital in the center. Even during this period, there began to develop the exchange of food and raw materials from the hinterland for manufactures produced in the center's growing factories. The laws of commodity exchange started, but became the dominant characteristic between center and hinterland only when capitalist development emerged into its next phase of absolute concentration of production. From about the last third of the nineteenth century to World War II, the long-run tendency for the profit rate to fall in the center, as a result of increased competition among capitals produced by the accumulation and centralization of capital, became a basic contradiction of the system and led to a new phase of imperialism. It took the form of harnessing and then changing a precapitalist mode in the hinterland to the new raw material and export requirements of the developing capitalist mode in the center. International trade and finance became important mechanisms in combatting the tendency of the profit rate to fall.

Colonialism established the necessary social and physical infrastructure for the primary accumulation of capital within the hinterland. A variety of political and economic instruments were used to create an available and cheap labor supply for export production and to widen the market for the center's output. Thus, the colonial state produced those internal forces that led to the effective organization of supply or cost conditions, and the demand for commodities was governed by external forces dependent on the accumulation of capital in the center. What a colonial country imported and exported, and at what price, or what emerged as its comparative advantage, was dependent upon political and economic forces within the center over which it had no control.

There is an important change in the third phase of imperialism corresponding to the transition from absolute concentration to monopoly capitalism in the center. The interest of capital in combatting the tendency of the profit rate to decline has not abated, but its international aspect has taken on a new form. Formal colonialism no longer exists. The multinational corporation, itself a product of this transition, has become the outstanding feature of the new international system that continues the historic dependence of the hinterland upon the center.

National independence after World War II produced a situation where the state was first controlled and then used by a precarious coalition of landed and merchant interests, in whose hands wealth was historically concentrated during the colonial process, to create a profitable environment for the transfer of their nonindustrial assets into industrial claims on wealth. The state through a variety of trade and fiscal instruments endeavored to manufacture a class of entrepreneurs who would be willing to hold and accumulate industrial assets.

Differential access to credit, foreign exchange earnings, import licenses, and tax incentives for a favored class indicates the state's endeavor to develop industry within a ruling oligarchy of landed and merchant wealth. Market imperfections indeed existed, but were created for the use of one class over another. The rate of return for this class was high, as indicated by the growing income gap, so long as an alliance between rural and urban poor was prevented. Thus, repressive governments are required to keep the rural and the mass of nonprivileged urban workers in place while an internal colonial policy is used to foster the accumulation of capital.

This industrialization effort has not produced an independent capitalistic class nor has it made the economy independent of the international economic system. In fact, during what might be called round one of the postwar period, the very type of forced industrialization experienced had deepened dependence on the center rather than reduced it. Increased imports of raw materials and capital goods and reliance upon the technology of the center are the results of import substitution. Indeed, the very survival of much of the manufacturing sector depends upon foreign inputs and, thus, the expansion of exports to finance these needs.

The national bourgeois class is as dependent upon foreign capital and its political power as is the industry established. The second phase of imperialism acted as a barrier to the development of local industrial capitalism and produced instead a class of traders, landed aristocrats, and government officials who had all the trappings and mentality of merchants, individuals more interested in the maintenance of their privileged position in the sphere of exchange than in seeking new forms of production to invest their accumulated surplus. They were the capitalistic children of the bourgeoisie of the center and would require a protected environment to develop, but they could not and cannot outgrow the environment and create one of their own. Their industrial experience begins within a setting of state-fostered oligopoly and monopoly power rather than competition, perhaps partly due to technical reasons of optimum plant size, but more likely because of the need for the state, as an engine of growth, to overcome a disadvantaged past. The process of capitalist development followed produced a new era of industry, but reproduced their dependence upon international relations of production over which they have no basic control.

The multinational corporation has become the chief agency in this third phase of imperialism, incorporating the local bourgeois class into its corporate hierarchy, as at best junior partners, and linking and integrating the hinterland's industry into a global network of capitalist production. Whatever legal organization is used to conform with national laws of ownership, capitals of the center use a variety of institutional mechanisms, e.g., foreign subsidiaries, joint ventures, and corporate devices (management fees, patent and franchise royalties, intracompany pricing, marketing fees) to effectively transfer profits to the center and maintain control over the production process. National industry may appear to be growing, but it is little more than national plants of multinational corporations whose local "owners" may have control over the day-to-day operations, but not over decisions on pricing, output, and investment. The structure of Canadian industry may be the future for the hinterland, but at present it looks more like Puerto Rico, a branch plant country of United States capital. In either case, the hegemony of the center has not been diminished. Yet for some countries, round one may be ending.

Taiwan and South Korea may be forerunners of a new form of dependent capitalist development in round two. The organization of industry, dominated by foreign capital, has already been established, and cheap labor power has been made available for wage labor employment in both agriculture and industry through the fragmentation of the natural economy in the agrarian sector. Politically these countries represent safe havens for capitals of the center to exploit the existing cheap labor supply because of their dependence on *U.S.* military assistance. This political stability and the economic reforms passed make it attractive and profitable for multinationals to exploit lower unit labor cost in these countries, as compared to the center, to produce and export manufactured commodities to the center and to other countries of the hinterland. Taiwan and

South Korea may represent a preview of the future as the import-substitution phase of round one gives way to the exports of manufactures of round two. This process completes both the dependency of production in the hinterland upon that of the center and the reproduction of colonialism without formal colonies.

The observed rise in employment of wage labor in these countries, generated by the rise in exports, indicates the qualitative and quantitative change in social relations of production. Individuals are increasingly forced to have the freedom to sell their labor power in the market. Correspondingly they become subject to the domination and uncertainty of international capital. The drain of surplus value continues. No doubt this new era is already undergoing change as frictions appear among competing capitals of the center, and the very proletarianization of the hinterland's labor force produces an endogenous agent of change. More analysis is needed to understand these forces now emerging. Yet the very lack of neoclassical development theory to understand how one class exploits another, duplicated in its lack of understanding of how one country can exploit another, makes it useless in this new endeavor.

WHAT HAVE WE LEARNED FROM ECONOMIC GROWTH THEORY?

Implications of Growth Theory for Trade and Development

By RONALD FINDLAY*

This brief survey of the implications of growth theory for trade and development is in three parts. The first discusses the Ricardian and Marxian approaches, the second is devoted to some well-known contributions of modern growth theory, and the third offers a hypothesis as to why all three frameworks are each inadequate to serve as explanatory schema for the major trends in the relations between the "center" and the "periphery" of the world economy.

I.

In assessing the impact of growth theory on trade and development, I find it useful to consider the doctrinal history of the subject. Modern growth theory is usually taken to begin with R. F. Harrod's essay of 1939, but we should not forget that David Ricardo was a growth theorist too. Technical relations between inputs and outputs, propensities to consume and to save out of different classes of income, and the determinants of the growth of the labor force over time were all fairly explicitly specified and the implications for the growth and distribution of the national income were rigorously deduced. While the assumptions chosen were of course radically different from those of contemporary writers, the analytical procedure and method were the same in spirit and in form.

The basic Ricardian model is usually formulated as a sequence of harvest cycles in an agricultural economy in which output is a function of the supply of land which is fixed and the supply of labor which is proportional to the stocks of corn held by capitalists as "advances to labor." Landlords get the marginal product of land for each acre that they rent out, and capital gets the marginal product of the labor that it supports minus the subsistence wage. Rent is all consumed and profits are all accumulated so that the labor force expands, raising the marginal product of land and hence total rent, while reducing its own marginal product, and hence the margin of profit for the capitalists, until it falls to the subsistence wage itself, at which point profits become zero and the stationary state is reached. The accumulation of circulating capital, which drives the system forward, is eventually checked by the inert force of something that cannot be indefinitely accumulated, the "original and indestructible powers of the soil." The Ricardian capitalist to whom, as Marx was to say later, accumulation was "Moses and the prophets" is ultimately forced to the ultimate indignity, which is to get back at the end of the year merely what he advanced at the beginning.

The way in which international trade can modify these long-run implications of the basic model is analyzed by Ricardo in his *Essay on the Influence of a Low Price of*

---

* Columbia University.

Corn Upon the Profits of Stock. His discussion there is of much greater interest in connection with the growth-trade nexus than his much more famous static analysis in the *Principles* involving the celebrated numerical example of England and Portugal exchanging cloth and wine. In this analysis, as formalized in Findlay (1974) drawing on the work of L. J. Pasinetti, there are two sectors in the economy, agriculture, with the characteristics described above, as well as manufacturing, which produces luxury consumption goods purchased by the landlords out of rent. Relative prices are determined by the requirement that the rate of profit be equalized between the two sectors. Repeal of the Corn Laws or opening the economy to international trade would result in less labor being used in agriculture, lowering rents, and raising the rate of profit. Manufacturing output will expand to provide the exports necessary to pay for the corn imports. Thus it would seem that international trade can avert the approach of the stationary state, since the higher rate of profit would permit a higher rate of accumulation. However, land is limited in the long run in the trading partners as well and so world accumulation and labor force growth must raise the relative price of corn in comparison with manufactures, thus raising rents and lowering the rate of profit. Ultimately the world economy as a whole must tend towards a stationary state. Trade can, therefore, postpone but not abolish the cessation of growth that results from diminishing returns.

It is interesting to observe that the opening of trade influences the rate of profit and hence the rate of growth in the opposite way for the two partners, raising it for the exporter of manufactures and lowering it for the exporter of corn, the reason being that the shift in income distribution is favorable for accumulation in one case and unfavorable in the other. The static gains from trade are shared mutually, but the dynamic effects are inversely related. The terms of trade, however, move secularly in favor of the agricultural exporter.

In spite of its obvious shortcomings, one must admire the way in which Ricardo was able to provide a simple analytical framework to relate growth, income distribution, and trade in such a sweeping way. His was truly a "magnificent dynamics."

Growth theory in the grand manner was continued by Karl Marx. In spite of the many Ricardian aspects of his thought, one fundamental difference between their systems is the fact that Marx did not bring the limited supply of land and diminishing returns into his scheme in any essential way. His biographers have informed us of Marx's love of Greek tragedy and perhaps his unconscious dramatic instincts rebelled at bringing down the tragic hero of his system, the capitalist entrepreneur whom he both admired and hated, by something as crude and obvious as limits of cultivable land. Like all good German romantics, Marx thought that nature could be transformed and could not by itself constrict the limitless progress of humanity. Technical progress, the genie in the bottle that Ricardo never found, comes on to the center of the stage in Marx's vision of capitalist development. Like the tragic hero, it is not external circumstances of environment that would destroy capitalism but the fatal flaw within, the "internal contradiction," as he would say. Capital accumulation and technical progress expand production possibilities while the "immiserization of the proletariat" that the process is supposed to create makes it increasingly difficult for the additional output to be marketed, leading to cyclical crises and depressions that get increasingly severe until they finally produce a proletarian revolution.

The international aspects of capitalist development and its impact on traditional societies produce ambivalent reactions in Marx. On the one hand he condemns the plunder and disruption that it brings, but he also welcomes the "battering down of Chinese walls" and the end of the millennial stagnation of the so-called "Asiatic mode of production" in which a superstructure of despotism and bureaucracy rests on a basis of self-sufficient village production, maintained by forced labor on irrigation and other public works. The British destroyed the weavers of Bengal, but they also brought the railways, and in Marx's opinion, India would never be the same again.

Later Marxist writers, including of course Lenin, brought in foreign investment and associated export booms as a way in which capitalism attempts to overcome its internal contradictions of insufficiency of effective demand due to the impoverishment of the proletariat. This literature stresses the negative aspects of the impact of capitalism on less developed areas, in which imperialism is seen as suppressing incipient industrialization in the interest of maintaining markets for the colonial powers. The most recent major contribution in this tradition was the stimulating work on the multinational corporation of Stephen Hymer, whose tragic death robbed our profession of one of its all too few original points of view.

II.

Growth theory was never a systematic concern of the major neoclassical writers and its modern revival by Harrod and E. D. Domar was inspired by Keynesian considerations of how to maintain adequate effective demand to match a growing productive capacity and labor force. Domar's contribution was to show that investment had to grow exponentially at a rate equal to the savings rate divided by the capital-output ratio if it was to generate the effective demand required to fully utilize the productive capacity that it created. Harrod contributed the concept of the "natural rate of growth" equal to the rate of population increase plus the growth of productivity, both assumed exogenously fixed, to which the actual growth of the economy had to conform if instability was to be avoided.

Though Harrod and Domar each came to it in different and subtle ways, their names, if not their ideas, were merged into the simple formula that the rate of growth of output was equal to the savings rate divided by the capital-output ratio. This formula was widely used in the various "development plans" that proliferated in the 1950's and 1960's. Typically a target growth of per capita income was added to the estimated rate of population growth to get a desired growth rate, which was then divided by an assumed capital-output ratio to get the required rate of saving. Fiscal and foreign assistance measures were then set to achieve this required savings ratio. Though it is now somewhat fashionable to deride these efforts, I believe that the widespread acquaintance with this simple relationship on the part of planners and administrators contributed towards coherence and consistency in the aggregative framework in which development planning was conducted. The reasons for failure or relative lack of success in most cases was inability to predict sufficiently accurately such things as the demand and supply of foreign exchange and the absence of adequate machinery for implementation and control at the project level.

Using the simple formula as it stands would seem to imply that growth is proportional to the savings rate and the reciprocal of the capital-output ratio. The constraint of the natural rate of growth, however, could be argued as not binding in economies with extensive rural and even urban underemployment. In a celebrated paper W. Arthur Lewis took an explicitly Ricardian approach to the problem of growth in a developing economy, arguing that the real wage of the "modern" sector is set by conditions in the much more heavily populated "traditional" sector of a "dual" economy. The growth rate of the modern sector then depends upon the fraction of profits that are saved, assuming that the wage is too low to permit any saving by workers. Employment can expand at a more or less constant wage rate in step with the growth of capital and at a rate above the natural rate of growth until such time as the underemployed pool of labor or "industrial reserve army" has been depleted.

The relationship between the growth rates of capital and output and the natural rate in a fully employed economy was determined by R. M. Solow (1956) who used the concept of a constant returns to scale aggregate production function with capital and labor as the inputs. He showed that the Harrod-Domar formula determined the growth rate of capital, with the growth rate of output a weighted average of the capital growth rate and the natural rate. With the capital-output ratio free to vary in response to changing relative factor prices, the capital growth rate converged in the long run to the natural rate. Hence, increases in the rate of saving could not permanently raise the growth rate of output above the natural rate, though the level of per capita output would be higher in the long run the higher the constant rate of saving. This result, together with the calculation in Solow (1957) showing that apparently 85 percent of the growth in per capita output in the United States was due to technical change instead of capital deepening, had the implication for development policy that the main thrust over the long haul would have to come from improvements in technology.

Since the developing countries presumably are able to draw on a vast backlog of new technology already available in the more advanced countries, this view could be regarded as having optimistic consequences for the growth prospects of the former group. The "green revolution" excitement of the early and middle 1960's reflected this enthusiasm about the possibilities of technological change for development. However, it soon became clear that the diffusion of technological change is itself a complex and resource-using process, and moreover, one about which we know very little. The quality of the labor force in the receiving country is one obvious factor influencing the rate at which technology can be borrowed, making a case for the priority of investment in human instead of physical capital. Much has also been made of the multinational corporation as a vehicle for the transfer of technology. Very little analytical work has been done in this area. It would seem that one possible approach is along the lines of a paper by E. S. Phelps and R. R. Nelson. The rate of technological change in the borrowing country could be made a function of the gap between the current levels of its own technology and that in the advanced countries, which can be assumed to change at some exogenous rate, the rate at which borrowing takes place depending upon such factors as the educational level of the labor force and the extent to which plants run by multinational corporations operate within the domestic economy, providing an opportunity for "learning by seeing."

The two-sector version of the neoclassical growth model presents a convenient framework for the formal integration of growth and trade theory. The Heckscher-Ohlin factor endowment approach to international trade was given its familiar two-factor, two-good specification in the 1930's and 1940's by Abba Lerner, Paul Samuelson, and others. H. Oniki and

H. Uzawa made one sector the capital goods sector and the other the consumption goods sector and produced a model of trade and growth in a two-country world economy with a common natural rate of growth for the two countries. The pattern of comparative costs changes over time in such a model along with the relative capital-labor ratios. Comparative advantage is thus not determined once and for all by a given endowment as in the traditional approach, but instead depends upon parameters such as the rate of saving and the growth rates of population and technological progress that can, within limits, be altered by policy.

The exclusion of natural resources from this model seriously restricts its applicability and relevance to such problems as the secular tendency of the terms of trade. As we have seen, the Ricardian model predicts that this will be in favor of the primary exporter while writers such as Raul Prebisch have taken the view that technological progress in economizing on raw material requirements and the substitution of synthetic materials for natural products more than offsets the effect of diminishing returns in the opposite direction. The neoclassical growth models as they stand are not able to even consider this important question.

For further investigations of trade and growth in the context of neoclassical and dualistic models, the reader may consult P. K. Bardhan and Findlay (1973).

III.

Growth theory, like the theory of anything else, has to be confronted with the relevant facts. In the present case the facts are the economic history of the last two hundred years or so since the Industrial Revolution in England transformed the world. What precise combination of economic, social, and other forces brought that singular event about is impossible to ascertain in any precise way and is beyond the scope of a narrowly technical subject like growth theory. Marxists may claim to have an answer, but one searches the literature on the "transition from feudalism to capitalism" in vain for any endogenous mechanism to account for it. Alternative theories of Max Weber and others are no more satisfying. Given that one exogenous impulse, however, one would expect to be able to construct a theoretical scheme that will do some justice to the manner in which the frontier of "modern economic growth," as Simon Kuznets calls it, spreads from the initiating "center" of the world economy to a receding "periphery" until the globe as a whole becomes a single interdependent system. Can growth theory be said to have provided, even modestly, the explanatory power that one would expect of such a scheme?

The answer, I think, must be in the negative and it is interesting to speculate why. One important reason, it seems to me, is that it is impossible to make any sense of this process without considering it in terms of a complex interplay between technological progress and the availability of natural resources. Yet, strange as it may seem, none of the three broad approaches to growth theory that we have surveyed looks at the problem in terms of *both* these fundamental determinants. Ricardo, we tell our students, was led to false prognostications because he ignored technical progress. Yet contemporary growth theorists, of either Cambridge, blandly ignore any mention of land or raw materials, assuming that somehow technological progress can ensure that steady growth can go on forever. To her credit, Joan Robinson refers to such a state of affairs as a "golden age" to remind us of its mythical character, but the tough problems of how to deal with natural resources in models of growth do not seem to have been faced by anybody. The current crises through which we are passing and the profound alteration in the balance of world economic power that is taking place are all manifestations of the simple fact that the earth's resources are finite, something that growth theory since Ricardo never seems to have recognized. David Landes suggestively entitled his fascinating book on the history of technological change since 1750 *The Unbound Prometheus*. We should not forget the price that Prometheus had to pay for stealing the fire from heaven.

The Theory of Economic Growth: A Critique and Reformulation

By DONALD J. HARRIS*

What has become of the modern theory of economic growth? In its dominant neoclassical form, the basic idea was that a capitalist economy is inherently capable of undergoing a sustained equilibrium of steady growth with divergences that are "fairly small, casual, and hardly self-accentuating" (R. Solow). This idea was at first starkly portrayed in a well-known parable constructed expressly for the purpose of conveying it. The idea was supposed to remain essentially the same after all the complications excluded from the simple parable were introduced. It turns out, however, upon further analysis, that this presumption is unfounded, once allowance is made for the heterogeneity of means of production which characterizes an advanced division of labor (E. Burmeister and A. R. Dobell, chs. 8, 9). Under these general conditions, not only is the neoclassical growth equilibrium not necessarily unique, but also the stability of the approach to any such equilibrium cannot be guaranteed. Efforts to resolve these problems have so far involved a resort to *ad hoc* assumptions that are unsupported by any systematic theoretical justification.

Admittedly, these analytical problems which the neoclassical theory faces are quite serious at a formal level. Moreover, they cannot be escaped by abandoning the simple parable as a bastard child and retreating into the supposedly more legitimate realm of neoclassical general equilibrium theory. For if there is such a thing as a neoclassical theory of economic growth, the substance of it must be capable of some form of coherent expression. Otherwise it remains the hollow shell of a system of differential equations.

Nevertheless, viewed on the plane of the system of neoclassical theory as a whole, these problems are of a relatively minor nature. On this plane the crucial question is, rather, whether that system of theory, *qua* theory, has anything at all to say about the process of accumulation in a capitalist economy. In its original and basic conception, neoclassical theory constitutes the process of accumulation as a process of "deepening the structure of capital," in which the saving decisions of atomistic individuals drive the economy to a stationary state where the ratio of the quantity of capital to labor is optimal and where there is no further inducement to save because the rate of profit (or rate of interest) has fallen to the level of the rate of intertemporal preference or the "cost of waiting" (K. Wicksell, J. Hirshleifer). What drives the economy in this conception are the intertemporal preferences of individuals engaged in exchanging consumption today for consumption tomorrow. The capitalist firm is seen merely as an intermediary between the individuals as suppliers of factors and the individuals as *rentiers* consuming their lifetime income. The basic objective of the economy as conceived in such a system is consumption; accumulation is an incidental feature of individuals' consumption decisions and comes to an end in the stationary state. The theory in this way denies the self-sustaining drive for expansion of capital as an essential feature of the capitalist mode of production.

---

* Associate professor, University of Wisconsin.

Continued expansion occurs in the neoclassical system only if it is assumed that there is an autonomous increase in factor supplies, consisting of the labor force, and autonomous changes in technology, both of which are unexplained *data*. In this respect, if continued expansion occurs it is for reasons that cannot be found within the theory and hence there is no *theory* of growth at all. Furthermore, the process of expansion (it is not so much a process as it is a "sequence of momentary equilibria"), to the extent that it occurs at all, is conceived essentially as a matter of piling up stocks of means of production (specific use values) either in the form of "putty" or as a heterogeneous collection of physical objects under the reign of Say's Law in an economy of simple commodity production (Burmeister and Dobell). In such a world, crises of overproduction and unemployment, booms and depressions, which are recurrent features of the entire history of capitalist development, do not arise except as temporary aberrations of the system. There is no identifiable class of workers displaced from property in the means of production who must depend entirely on employment in capitalist production, with its ups and downs, for their economic survival. It is therefore difficult to see what real historical phenomena, if any, this system of thought is intended to explain.[1] The central analytical question which is treated throughout all variants of the theory remains, not one of the historical laws of motion of capitalism, but rather one of the efficient allocation of resources in accordance with consumers' preferences (E. Malinvaud). This is evidently the whole basis of the singular concern of neoclassical theory with the problem of optimal growth.

It is not possible to pursue further in this short space the direct critique of the neoclassical theory. For this it would be necessary to locate in the basic conceptual structure of that theory, in the neoclassical theory of subjective value, the internal obstacles to its ability to grasp the process of capitalist production as a whole. This work is being pursued in different ways elsewhere (Harris, 1973 and 1974) and by others (e.g., J. Robinson, 1971, D. Levine, and E. K. Hunt and J. G. Schwartz). The time has come, however, to seek to establish the theory of economic growth on an entirely different footing. Some partial elements for such a reconstruction of theory are to be found in recent work, especially that of Robinson, and in earlier work of M. Kalecki and J. Steindl. But for a truly fundamental and integrated system of analysis, we have to turn to the tradition of Karl Marx who was the theorist of economic growth *par excellence*.[2]

Speaking broadly and briefly, a theory of economic growth is to be conceived as an explanation of the causes of the contradictory development of the capitalist mode of production, based on the observable historical reality of an immense expansion of productive forces and revolution in methods of production under capitalism combined with the persistence of unevenly developed sectors over large areas of the capitalist world and with periodically recurring crises affecting all or most of the major branches of industry. What is to be explained is this specific form of capitalist development: the nature of the forces which propel the system forward in this way and which account for the particular (contradictory) form of its forward movement. A theory of growth is, in this view, *a theory of the expanded reproduction of the capitalist mode of production on a world scale*. There are three central and interrelated elements involved in the construction of such a theory. These are: (1) the process of production of value and surplus value, at the heart of which is the conflicting *social* relation of capital to labor beginning in production and extending to other spheres; (2) the process of capital accumulation involving a continual drive for expansion of capital accompanied by changes in methods of production; and (3) the role of the state as dictated by the requirements of reproduction of capital and the contradictions associated therewith.

---

[1] If we examine as against this the humble beginnings of the modern theory in the works of R. F. Harrod, E. D. Domar, Sir John Hicks, and others of the business cycle theorists (see R. A. Gordon and L. R. Klein), we find that this work, though it did not get very far as a whole, was genuinely concerned to explain real phenomena in contemporary capitalism. Among other things, it failed specifically to integrate a theory of growth and the business cycle as aspects of the same phenomenon. In later work the problem of the business cycle was altogether displaced by a preoccupation with the properties of steady-state growth. There is no mention of that problem at all in N. Kaldor's definitive list of the "stylized facts" appropriate to the construction of a theory of economic growth.

[2] I exclude here the tradition of classical political economy, despite the fashion of holding up that tradition as the paragon of growth theory. This is because the classical economists failed to consummate a theory appropriate to the conditions of industrial capitalism. Their ideas were essentially limited to the conditions of an agrarian capitalism, without significant change in methods of production (or foreign trade), in which, due to the limited quantity and diminishing fertility of the soil, growth is arrested by increasing costs of production of wage goods. The Malthusian variant of this theme has, rather curiously, risen to prominence again in recent times.

There is no room in this view for conceiving of a separate and distinct theory of underdevelopment, as commonly understood, except as a theory of the transition from noncapitalist production to capitalism. Some glimpses of the latter are beginning to emerge, mostly through the work of anthropologists (E. Terray and M. Dobb). There is room, however, for a *theory of uneven development* under capitalism, encompassing international trade and imperialism. Some steps are being taken in this direction (see S. Amin and A. Emmanuel).

It is impossible to go into the details here. Instead, I sketch below some (limited) features of the general approach as applied to analysis of the problem which gave impetus to development of the modern theory of economic growth beginning with Harrod, that is, the problem of capitalist crises.

I. Surplus Value, Accumulation, and Capitalist Crises

The analysis utilizes a formal scheme the purpose of which is to constitute on an abstract and simple level the process of reproduction of the aggregate social capital in an expanding capitalist economy. Crises emerge as a result of the failure or inability of the system to satisfy completely the requirements of continued reproduction.[3] This failure is shown to derive from one or another of several *proximate* causes.

The starting point of the analysis is the process of production of value and surplus value under conditions of capitalism. Production consists of the production of commodities through employment of labor and means of production which are themselves the product of labor.[4]

From the value produced in a day's labor, a proportion, say ω, goes to sustain and reproduce the labor power of the worker. The rest constitutes surplus value or unpaid labor. ω is a socially determined magnitude. It is the labor value of the "necessaries" required to maintain the worker at a given standard of life as determined by historical and social conditions, including in those conditions the organized struggle of the workers vis-à-vis the capitalists, i.e., the conditions of the class struggle.[5] The rate of surplus value (or rate of exploitation), ϵ, is related to the value of labor power as

---

[3] This analysis does not deal with the mechanism of the business cycle, which represents the practical working out of the crisis, but with the broad conjunctures which may at one time or another underlie the existence of a crisis.

[4] The problem of fixed nonproduced resources (such as land) arises at a lower level of abstraction and, for purposes of a theory of accumulation, has to be dealt with in the context of an analysis of technical change which is being left out of account in this discussion.

$$\epsilon = (1 - \omega)/\omega \tag{1}$$

and it is the same in all sectors as long as ω is uniform.

Capitalists appropriate surplus value at the rate ϵ and competition dictates that the total amount of surplus value is redistributed among them at a uniform rate in proportion to the total price of their respective capitals. The rate of (net) profit, r, is thus the outcome of a market process of free exchange in which competition reigns because capital is freely mobile and prices of commodities are equated to their costs of production consisting of wages, plus profits, plus depreciation. In the equilibrium conditions of the price system, there exists a well-defined relationship between the rate of profit, the value of labor power, and the embodied-labor ratios corresponding to the given technique of production.[6] In the simple case where there are only two sectors of production (see Appendix), this relationship takes the form:

$$r = \rho(m_1, m_2, \omega). \tag{2}$$

Given the value of labor power ω and the embodied-labor ratios (m_1, m_2), the rate of profit consistent with the conditions of production and reproduction is uniquely determined from (2). The associated rate of exploitation is given by (1).

Consider now the requirement for overall balance of production and demand. In the aggregate, capitalists save a proportion s of their total profits.[7] Workers' saving is for consumption and their net saving as a class is zero. Investment is divided between increments to capital in each sector. For balance in the flow of output and expenditure it is required that savings equal investment. Thus,

$$sr = g = l_1 g_1 + l_2 g_2, \quad l_1 + l_2 = 1 \tag{3}$$

where g is the overall rate of accumulation, g_1, g_2 are the rates of accumulation in each sector and l_1, l_2 are appropriate weights. For the sake of simplicity we confine attention to the case of *balanced* growth where it is assumed that $g_1 = g_2 = g$.[8]

Next consider the investment plans of the capitalists. These may be represented as an increasing function of the expected rate of profit, r^e, and it is assumed for simplicity that the expected rate of profit is equal to the realized rate. Assume also that there is a minimum rate of profit below which capitalists do not invest. Thus,

---

[5] This is obviously not all there is to be said about the role of class struggle in the operation of the capitalist economy. The determination of the real consumption of workers is simply one point, and a significant one, at which it enters the system. Other relevant points in production are, for instance, the length of the working day and the technical conditions of the labor process. Further analysis would require introduction of these complications and recognition of the fact that, in practice, the wage bargain is conducted in terms of money wages while being tied to a cost of living index. When the workers' struggle is assumed to center around the share of wages in national income rather than around the real wage, the analysis would turn out rather differently (Harris 1972). It could be argued that the former is the case which is appropriate to the conditions of modern capitalism (Robinson 1973). What all of this points to is the need not only for abstract theoretical analysis but also for more concrete historical study of the labor-capital relation in modern capitalism.

[6] In the light of the work of P. Sraffa, this proposition can now be readily understood as one which holds in the *general* case of production of many commodities with or without joint production (in the form of fixed capital) and with one or many alternative techniques of production.

[7] This assumption is consistent with a more concrete formulation of the behavioral conditions in terms of corporations which retain a proportion α of total profits and distribute the rest to a rentier class who save at the rate s_r out of distributed profits. The saving rate of the whole capitalist class is then, $s = \alpha + s_r(1 - \alpha)$.

[8] There is, of course, no *empirical* basis for the assumption of balanced growth. Use of this assumption requires justification on other and quite different grounds. The rationale is strictly a *theoretical* one and is to be found in the specific focus of the analysis at this stage. In particular, the analysis is concerned with the reproduction and expansion of capital *as a whole*. For this purpose, the assumption of balanced growth is a convenient one. It leaves aside the problem of relative expansion of different sectors of capital, this being the purview of a theory of *uneven* development. For an equilibrium of balanced growth to exist, initial conditions must be appropriate. This requires a specific allocation of labor and means of production between the different sectors.

$$g = g(r^e), \qquad r^e = r. \tag{4}$$

This formulation is readily recognized to be a short-hand though fully adequate expression for a complex process.[9] It leaves aside the specific concrete conditions which may at one time or another govern the state of investment activity. For present purposes these may be regarded as causing shifts in the function $g(.)$.

The only remaining condition to be introduced is that concerning the availability of labor for production. Accumulation at any positive rate with the given technique of production sets up an increasing demand for labor. The requirement of an increasing labor force to match this demand is an independent condition of the problem.[10] Where the labor force grows at the rate ℓ this condition is

$$g = \ell. \tag{5}$$

These formal relationships constitute the basic structural conditions governing the expanded reproduction of capital. Consistency among them, taken together, is required for the process of reproduction and circulation to be smoothly carried out. Inconsistency among them accounts for a rupture or a crisis in the process. There are different possible types of crises and underlying causes, depending on the particular pattern of such inconsistency. These are illustrated with the aid of a diagram.

The left-hand quadrant of Figure 1 describes the relationship between the rate of profit and value of labor power for given technical conditions. At a given value of labor power, $\omega=\omega^*$, and associated rate of exploitation, the equilibrium rate of profit which allows competitive redistribution of the surplus among capitalists is $r=r^*$. In the right-hand quadrant the ray *OG* defines the relationship between the growth rate and profit rate which is consistent with overall balance of production and demand when capitalists save at the rate s. Call this the *profit realization curve*. It represents the profit rate that would be realized from sales of the product at a given rate of accumulation. It has a maximum at (r^*, g^*) corresponding to the existing rate of exploitation. The curves $g(r)$ represent the planned rate of accumulation as a function of the (expected) rate of profit. Three such

---

[9] On a social and historical plane, this process encompasses not only the inducement mechanisms of the market operating through obsolescence and technical change in methods of production, as well as the accelerator-multiplier effect of investment itself and the effect of wars, but also the social mechanisms determining entry and mobility within the capitalist class and various methods of "primitive" accumulation. While all of this is not capable of being captured in the simple formula of an investment function, it does require further articulation and analysis in theoretical terms. There is already a substantial basis for such an analysis in the works of Kalecki, Steindl, P. Sylos-Labini, and P. Baran and P. Sweezy, among others. Nevertheless, these more specific considerations are not strictly necessary at this stage of the analysis. This is again because of the particular level of abstraction at which the analysis is situated, that is, at the level of the reproduction and circulation of capital as a whole. At this level it is fully adequate to recognize that the drive for profits is the basic motive force underlying the expansion of capital. In this respect investment activity springs from the most fundamental characteristic of capitalist production and not from any arbitrary subjective or psychological motives (e.g., time preference) on the part of individuals.

[10] Expansion of the available labor force may take place in a variety of ways which are *internal* to the system of production as, for instance, through increase in the number of hours worked per worker or through absorption of the existing reserve army of labor viewed on a world scale (by means of immigration and capital export). It may take place also *on the margins* of the system of capitalist production as, for instance, through erosion of household work and other noncapitalist forms of production. In these and other ways accumulation creates the labor supply required for its own continuation. The connection is, however, neither fully automatic nor perfectly synchronized.

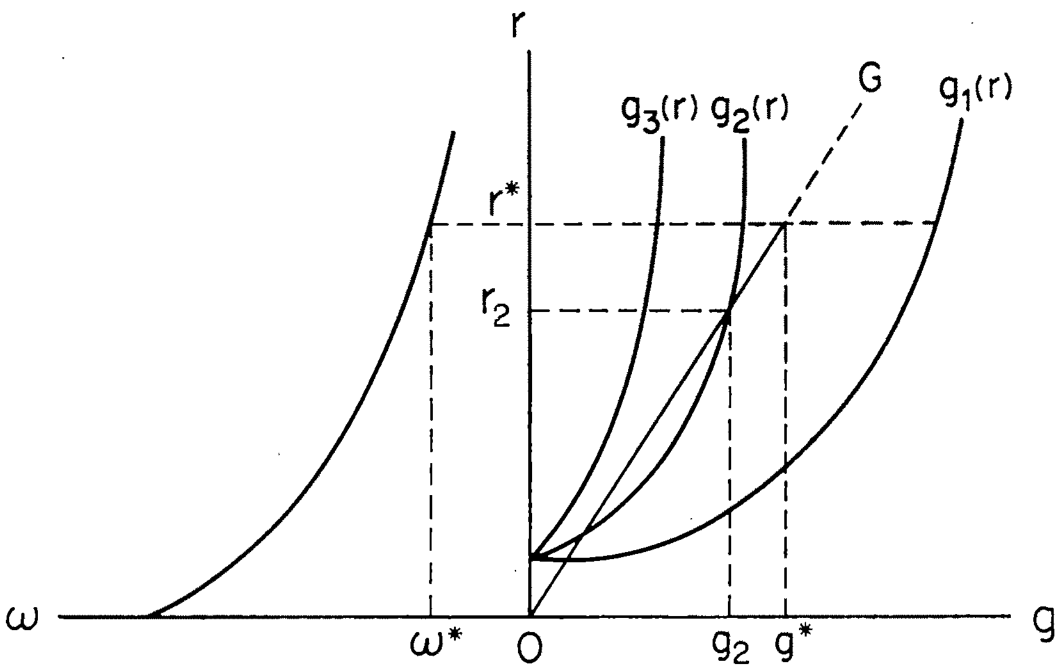

FIGURE 1

curves are drawn, each representing a different state of investment plans corresponding to a particular set of historical conditions. Consider the meaning of each case.

A. Case 1

When investment plans are at the level corresponding to $g_1(r)$, accumulation at any positive rate above some minimum enables the capitalists to realize a rate of profit which induces them to expand at a higher rate. The capitalists are seeking then to increase the rate of accumulation. With a higher rate of accumulation, a higher rate of profit would be realized and the capitalists would plan to grow at a still higher rate. There is, however, an upper limit to the rate of profit and rate of accumulation given by (r^*, g^*). At this limit the capitalists are, so to speak, straining at the bits to expand the size of their capital, $g_1(r^*) > g^*$. They are held in check by the rate of exploitation corresponding to the existing conditions. Under these conditions the planned rate of accumulation cannot be sustained. We may say that there exists a crisis. It is due in this case to excessive accumulation in relation to the pool of available surplus. It may be manifested, for instance, in the form of an inflationary spiral (compare Robinson's concept of an inflation barrier).

The actual rate of accumulation could be higher if the value of labor power were lower, thereby permitting a higher rate of profit. This would require a readjustment of existing class relations as related to the costs of reproduction of labor. Alteration of the technique of production, such as to lower the embodied-labor ratios and the labor embodied in wage goods, would have the same effect.[11] The actual rate of accumulation could also be higher if capitalists were to save at a higher rate. Otherwise, the only possible basis for resolving the crisis is through an adjustment in the rate of accumulation itself.

---

[11] It is the possibility of such an adjustment in production coefficients, viewed singularly as a matter of substitution along a given production function, which constitutes the central idea of the neoclassical parable.

B. Case 2

This is the case of investment plans corresponding to $g_2(r)$. Under such conditions, there exists a point (r_2, g_2) such that, when capitalists accumulate at the rate g_2, the realized rate of profit is just sufficient to induce them to continue to accumulate at the same rate. There exists an equilibrium, in this sense, with respect to the overall balance between production and demand. At the same time, however, the realized rate of profit is less than that which is allowed to them at the existing rate of exploitation, but the latter cannot be realized. Thus there exists a crisis. Call this a *realization crisis*. It may manifest itself, for instance, in a deflationary tendency (under competition) as prices fall below values and the rate of utilization of productive capacity declines below normal.

The realized rate of profit could be higher if the level of investment plans were higher than $g_2(r)$, or if the capitalists were to consume at a higher rate. In this sense, a realization crisis is due either to underinvestment or underconsumption on the part of capitalists, or to both. It is a matter of interpretation to which the analysis at this level is indifferent. Whatever the case, it is evident that there is no connection between the realized rate of profit and consumption on the part of workers. A higher level of workers' consumption leaves the realized rate of profit at the same level but *reduces* the rate at which capitalists as a whole can appropriate surplus value. In any event, this cannot come about without an adjustment in the prevailing class relations.

C. Case 3

With investment plans at the level corresponding to $g_3(r)$, the system is in a process of decelerating to a condition of zero growth with the realized rate of profit at its minimum level. There exists what we may call a *stagnation crisis*. It may be viewed as a degenerate case of a realization crisis.

D. Case 4

What if the state of investment plans were such as to correspond to a curve which passed through the point (r^*, g^*) from below? Then, at g^*, the realized rate of profit equals that which is appropriate to the existing rate of exploitation and is exactly what is required to maintain accumulation at the rate g^*. The situation need not, however, be fully consistent with equilibrium. This is because the requirement of a labor force to match the expanding demand for labor may not be fulfilled. The system may be in the course of exhausting the available reserve army of labor, being unable to replenish it sufficiently through internal or external means. Alternatively, the reserve army may be expanding because the rate of accumulation is too low to absorb the labor which is becoming available. Whatever the case, it is to be expected that each of these possibilities would, in turn, have effects on the rest of the system. These effects are likely to operate through variations in the bargaining power of workers and therefore on the rate of exploitation, with consequent feedback effects on the rate of accumulation. In this way the mechanism of operation of the reserve army of labor turns out

---

While it would be foolish to deny the technical feasibility of such adjustments, it is quite another matter to raise this to the level of a sufficient or even necessary condition for the resolution of a crisis. Because means of production are technically specific and particular patterns of organization of work and hierarchical relations of production are built around them in the factory, changes in methods of production are neither costless nor instantaneous. Neither are such changes a purely technical matter; they run up against the organized resistance of the workers.

to be crucial for the system as a whole, perhaps dominating every other form of crisis (Sweezy, p. 150).

Apart from the foregoing, there is more that can be said with this simple scheme. For instance, it is easy to recognize crises due to disproportionality between production of means of production and means of consumption. The role of monopoly, associated with different sectoral rates of profit, can be considered. To complicate the analysis, we have to introduce the conditions of technical change, the role of money, and so on. Further analysis would also require explicit recognition of the fact that the wage bargain is conducted in terms of *money wages*. The analytical difficulties are compounded when the problem of the state (an underdeveloped area of theory) is introduced. The objective of the analysis throughout is to provide historically based explanations as to why one or another set of crisis conditions comes to dominate the process of expansion of capital, to account for the mechanisms through which the crisis is resolved, and to explain the associated structural changes which occur in the system as it moves from one crisis to another.

Enough has been said here to indicate some broad features of the theoretical analysis. Meanwhile, yet another economic crisis is occurring in the capitalist world.

APPENDIX A

Let there be two produced commodities, each produced with one of them (number 1) and labor. The other (number 2) is consumed. There is a single, uniform period of production and stocks are used up in the period. For their maintenance and reproduction, workers consume a given quantity b per unit of labor. Labor values embodied in production of commodity i and labor power are

$$\lambda_i = a_{0i} + a_{1i}\lambda_1 = a_{0i} + A_{0i}, \qquad i = 1, 2$$

$$\omega = b\lambda_2$$

where a_{0i} are direct labor coefficients, a_{1i} are stocks and A_{0i} indirect labor. The rate of surplus value is

$$\epsilon = (\lambda_i - a_{0i}\omega - A_{0i})/a_{0i}\omega = (1 - \omega)/\omega.$$

In the price system:

$$p_i\lambda_i = (p_1 A_{0i} + p_2 a_{0i}\omega)(1 + r), \qquad i = 1, 2$$

where wages are paid out of capital and p_i are prices per unit of value. Setting $p_2 = 1$ and solving for r gives a quadratic from which, taking $r > 0$,

$$r = \rho(m_1, m_2, \omega), \qquad m_i = A_{0i}/a_{0i}.$$

Growth Theory from an Evolutionary Perspective: The Differential Productivity Puzzle

By RICHARD R. NELSON and SIDNEY G. WINTER*

This is a further progress report on our efforts to develop a theoretical structure capable of integrating what is known about processes of technical change at the level of the firm or the individual invention and what is known about technological advance as reflected in industry or economy-wide time series data on output and inputs (see Nelson and Winter, 1973 and forthcoming). Our endeavor is motivated by a belief that a theoretical structure that integrates these two kinds of knowledge would be useful in enabling better understanding of certain important phenomena that have proved difficult to comprehend within traditional models. Prominent among these phenomena, and the focus of this paper, are the vast disparities in various measures of productivity growth and technical change across different sectors. To cite illustrative numbers (from J. Kendrick's 1973 study), the yearly change in output per worker (1948–1966) was 5.6 percent in farming, 4.6 percent in mining, 2.9 percent in manufacturing. Within manufacturing, yearly productivity growth ranged from 6.0 percent in chemicals to 1.7 percent in leather products.

The great intersectoral differences in growth experience clearly are a puzzle for growth theory. Nor is the puzzle strictly intellectual. While W. Baumol may have put the matter too emphatically, consideration of rapid productivity growth sectors and slow productivity growth sectors suggests strongly that many of the nation's problems relate to sectors where technological advance (using that term to serve as a proxy for productivity growth) has been slow.

There have been a number of attempts by economists to explain cross-industry differences within the framework provided by traditional neoclassical theory. Kendrick's 1961 study, particularly the work of N. Terleckyj contained in that study, set the style for much of this work. Roughly speaking, the technique has been to regress a measure of productivity growth against various industry variables, particularly research and development (*R&D*) spending of various sorts. Recent studies have broken *R&D* spending in an industry into self-financed and government-financed and have tried to account for the effect of *R&D* expenditures by supplying industries. The research has shown that industries differ greatly in the magnitudes of different kinds of research and development that feed into them and that these differences are related to differences in the growth of productivity. (For a good survey, see Terleckyj.)

The studies have been useful and provocative, but have not cut very deep. Clearly there are severe specification problems. The regression equations involve complex interactions in which factors influencing the demand side and the supply

side of the technical change process are intertwined and confounded with other forces. There is a tangle of causations, from *R&D* to productivity growth, from productivity growth and lowered prices to growth of output, from growth of output in the presence of scale economies to productivity growth, from expansion of the industry to greater incentives for research and development, and so on.

Even if it were granted that causation runs, at least in part, from research and development spending to enhanced productivity, what explains the great differences in (direct and indirect) *R&D* spending across industries? Among the range of possible explanations, two stand in stark contrast regarding their implications. One is that research and development activity is more powerful when directed toward the technologies of certain industries than toward the technologies of others; therefore, the disparities in rates of technical progress reflect some kind of innate differences in ability to advance efficiently the different kinds of technologies which *R&D* allocation decisions rationally reflect.

A second explanation (not mutually exclusive) focuses on differences in institutional structure that influence the impact of research and development on productivity and the extent to which *R&D* spending is optimal. The proposition is that the effectiveness with which *R&D* output is screened and employed varies among industries. Moreover, industries also differ significantly in the extent to which patent rights and other protections internalize the returns to inventions that flow out of firm *R&D* spending, and in the extent to which government subsidization permits the undertaking of high-valued research and development projects where externalities are important. Needless to say, the differences in these explanations matter profoundly in terms of their policy implications.

In order to probe the issues it would seem valuable to look beneath the industry time series data and analyze the more micro aspects of technical change in the different sectors: the sources of key inventions, their costs and who bore the costs, the motives of the organizations in the sector, the constraints under which they operate, how new technology is screened and spread, etc. Without arguing that it is impossible to enrich the basic neoclassical model so as to do this, for reasons discussed at length elsewhere (Nelson and Winter, forthcoming) we believe it more straightforward to work within a set of assumptions that in some ways narrow and in some ways broaden those contained within the more traditional model. We do not want to argue about whether our proposal really is a special case of traditional theory. Rather, the question we want considered is: Is this a fruitful way to theorize?

Our theoretical focus is on the following three questions: What are the sources of productivity growth in firms? What is the nature of the technological advance process? How can we characterize the way in which new technology is screened and spread throughout an economic sector? Put simply, we propose that the dominant source of productivity growth in a firm is new technology, that the processes that generate technological advance tend to operate stochastically and locally, and that selection and spreading forces in a sector work out rather slowly over time. In combination, these commitments represent the starting points of a "technological mutation" theory of changes in the characteristics of firms, with a "selection environment" operating on the new technological mutations—in short, an "evolutionary theory." But we have a lot more in mind than merely a metaphor.

Within an evolutionary theory, productivity growth is explained, in an accounting sense, in terms of, first, the generation of new technologies and, second, changes in the "weights" associated with the use of different existing technologies. We have been trying to model the stochastic processes that generate new technology in order to identify the factors that might explain why certain kinds of technical advances might be more likely than others. But the aspect of our work we want to sketch at more length here is the characterization of the selection environment for a new invention. Given a flow of new technologies, the selection environment determines how relative use of different technologies changes over time. The selection environment influences the productivity growth generated by any given invention, and it also influences strongly the kinds of *R&D* that firms in the industry will find profitable.

Consider an invention-innovation that has been introduced to the economy—for example, the first model 707 aircraft produced by the Boeing Aircraft Company, a new seed variety tried by a farmer, a pioneering doctor trying a new anticancer drug, the first use of "open classrooms" in a school system. A necessary condition for survival of an innovation is that it be perceived as worthwhile by the organizations that directly determine whether it is used or not. If the innovation is to persist and expand in use, the firm or farm must find a new product or process profitable to produce or employ, the doctor must view the treatment as efficacious, the school system must be persuaded that the new classroom technique is good educational practice and worth the cost. Sectors obviously differ greatly in terms of the nature of the organizations that ultimately must decide on worth and particularly the salient objectives that determine worth.

However, the question of whether or not the organizations (firms) find the innovations worthwhile depends not only on the objectives of the firms. In almost all economic sectors the firms—for-profit private organizations, public agencies, individual professionals—are subject to monitoring mechanisms that partly determine whether an innovation scores well or poorly according to the objectives of the firms and that may impose more direct constraints on firm behavior. A key part of this monitoring mechanism involves the individuals or organizations who are the demanders or beneficiaries of the goods or services produced by the firms in the sectors. Thus, the profitability of 707 aircraft to Boeing depends on how the airlines react to these planes. The seed must produce corn that is profitable at prevailing prices. Patients must agree to the new treatment, etc. In some sectors there are additional constraints imposed on the individual firms by agencies assigned a legal responsibility to monitor or regulate the activity of the industry. Thus the Boeing 707, before it could be put into commercial use, had to pass Federal Aviation Agency tests. New pharmaceuticals are regulated, etc. Selection environments differ greatly in the structure of demanders and monitors, and in ways their reactions feed back to influence the desirability of a particular innovation to the firms in question.

Industries differ not only in the objectives of the firms and demand and regulatory constraints facing them. They also differ in the relative importance of the mechanisms by which innovations, accepted by that environment, spread. There are, roughly speaking, two distinct kinds of mechanisms for the spread of an innovation. One of these is greater use of an innovation by the firm that first introduces it. If the firm produces a variety of products or undertakes a variety of activities, this may occur through substitution of the new activity for older ones. Or the firm may grow by investing new resources. In sectors which involve a number of administratively distinct organizational units on the supply side, there is a second innovation-spreading mechanism that needs to be considered—imitation. Imitation of certain innovations may be deliberately spurred by the institutional machinery: thus the agricultural extension service encourages widespread adoption by farmers of new seed varieties. Or the institutional machinery may deter or block imitation, as the patent system blocks the adoption by one firm of patented innovations created by a competitor. Industries clearly differ greatly in the importance of these two mechanisms and how they work.

We propose that a rigorous general model of the selection environment can be built from specification of these three elements: the definition of "worth" or profit that is operative for the firms in the sector, the manner in which consumer and regulatory preferences and rules influence what is profitable, and the investment and imitation processes that are involved. In the remainder of this paper we shall discuss some important qualitative differences in sectoral selection environments that become the focus of attention once one poses the theoretical problem in the way we have. Market sectors differ significantly among themselves. And many sectors involve important nonmarket components that have special characteristics. While we have not yet attempted modeling to capture the kind of differences in fine structure we shall be describing, this is high on our agenda of business.

The perception that market competition in a sector operates like a selection environment was explicit in the writings of many of the great nineteenth and early twentieth century economic theorists. J. A. Schumpeter was well within the classical tradition. In a stylized Schumpeterian evolutionary system, there is both a carrot and a stick to motivate firms to introduce "better" production methods or products. Better here has an unambiguous meaning: lower cost of production or a product that consumers are willing to buy at a price above cost. In either case the criterion boils down to higher monetary profit. Successful innovation leads to both higher profit for the innovator and to profitable investment opportunities. Thus profitable firms grow. In so doing they cut away the market for the noninnovators and reduce their profitability which, in turn, will force these firms to contract. Both the visible profits of the innovators and the losses experienced by the laggers stimulate the latter to try to imitate.

Both expansion of the innovator and imitation by competitors are essential aspects of the Schumpeterian process. In the standard descriptions of dynamic competition, expansion of the innovator is likely to be stressed. It is surprising, therefore, that the relationship between innovation and investment has not been subjected to more serious empirical investigation. While almost all theories of firm investment would lead one to expect a positive relationship between successful innovation and investment, this has not been tested in the major studies of investment behavior. The exceptions are studies where the author's basic hypothesis is oriented around the Schumpeterian interactions. D. Mueller does find that lagged *R&D* expenditure by a firm has a positive influence on its investment in new plant and equipment. E. Mansfield's studies (1968) also give support for a "Schumpeterian" view. Perhaps his most interesting results involve comparisons of firm growth rates, where he finds that innovating firms tend to grow more rapidly than the laggers. However, while the advantage of the innovators tends to persist for several periods, the advantage damps out with time, apparently because other firms have been able to come up with comparable or superior innovations.

In contrast to the sparseness of studies of the relationship of investment to successful innovation, there have been a large number of studies which have focused on the spread of innovation by imitation in profit-oriented sectors. It is not useful here to review the details of these studies, save to note that many of them have documented the role of profitability of an innovation in influencing the speed with which that innovation spreads. (For a good survey, see Mueller 1967.) In most of the cases studied, the innovations were inputs produced by a supplier and the early adopters were not in a position to block subsequent use by their competitors. In some instances this was not the case. For example, a glass producing company, Pilkington, holds the basic patents on the float glass process and presumably had an interest in limiting diffusion to other firms except where Pilkington was blocked from the market. It is interesting that the analysts of diffusion have not always been cognizant of these differences.

It also is quite surprising that in no study of which we are aware has there been an attempt to study the expansion of the innovator and imitation of the innovator together. It would seem apparent that, in order for a market selection environment to work effectively, a rather fine balance is required between the two mechanisms. Preservation of competitive structure in the face of innovation is delicate. A. Phillips' description of competition in the industry that produces aircraft for commercial airlines reveals one extreme. The "expansion of the successful innovator" mechanism works powerfully here. This is a sector in which firms are able to expand capacity rapidly and where it is costly and time consuming to imitate another company's successful product. Further, demanders are quite sensitive to product quality and cost. In this institutional regime, a company that comes up with a superior product has a great advantage over its competitors, and because of the lags and cost of imitation, other firms may be forced out of business. And indeed, it appears that successful innovation has come close to destroying competitive structure in the civilian air frame industry.

On the other hand, the efficacy of Schumpeterian competition requires that firms be able to achieve significant size and that imitation not be too easy. Consider the situation in agriculture where it is very difficult for a successful firm to expand significantly and rapidly because of the cost and complexity of purchasing particular pieces of adjacent land. This puts the full burden of the spread of profitable new technology on imitation mechanisms. But at the same time it limits the profitability to any individual farmer of innovating and thus reduces the incentives to search out new techniques and to take risks. Implicitly this has been recognized. An elaborate subsidized mechanism has developed to disseminate widely among farmers information regarding the best new techniques.

While economists have concentrated their attention on market sectors, research on the selection environments of nonmarket sectors has been undertaken principally by anthropologists, sociologists, and political scientists. This in itself would lead to some significant differences in focus and analysis. But to a considerable extent the differences in analysis reflect real differences in the selection environments.

A hallmark of nonmarket sectors is that the separation of interest between firms on the one hand and consumers and regulators on the other is not as sharply defined as in market sectors. The relationships between a public agency, like a school system and its clientele (students and parents), and sources of finance (mayor, council, and voters) simply do not have that arm-distance quality that marks the relationships between the seller and potential buyer of a new car. The public agency is expected to work in the public interest of its own volition and, indeed, to play a key role in the articulation of that interest. This is so in many nominally "private" sector activities, like the provision of medical services by a doctor. The doctor is not supposed to make his decisions regarding the use of a new drug on the basis of whether this will profit him, but rather on his expectation of how this will benefit his patients. This is not to say that, in fact, interests of firms and consumers always are consonant. In most nonmarket sectors (as in market sectors where competition is lax), the firm has a good deal of discretionary power regarding what it is to provide, and the customer may have little direct power to reward or punish performance.

In any case, the motivations of the firms in the sector are not assumed to be monetary profit. Analysis of the operative values of the firms, therefore, should be a centerpiece of studies of nonmarket selection. This makes analysis difficult. As in the theory of consumer behavior, as contrasted with the theory of the firm, tastes matter; these may be hard to analyze, and they may not be stable. Thus in the J. Coleman, E. Katz, and H. Menzel study of the diffusion among physicians of a new pharmaceutical, the authors did not even attempt to specify in what ways the new pharmaceutical was superior medically to preexisting alternatives. K. Warner's study of the diffusion of cancer chemotherapy reveals doctors trying to assess the patient's best interest, but often having few objective criteria to go on.

In sectors that involve significant regulatory or political controls or division of responsibility, there is an additional difficulty in analysis of the operational definition of worth. Many different parties may have to go along before an innovation can be operative. In L. Friedman's study of bail reform, the courts and the police both had to agree to the proposal, and legislative agreement was necessary where budget was involved. Thus collective decision processes are involved. The interaction of firms, and demanders and monitors, certainly is more subtle than in market sectors.

Nonseparation of suppliers and demanders leaves little room for firms to compete among each other for consumer dollars. Because of this innovations must spread largely through imitation across the spectrum of noncompetitive firms producing the goods or service in question. At the same time there is no incentive for the innovating firm to deter imitation. Organizations that cannot expand into the terrain of others and know that others cannot encroach on their territory have little to gain from preventing others from adopting their successful innovations. Indeed, in most of the sectors under consideration here, there are formal arrangements for cooperation and the flow of information among the firms.

Consider the quasi market for the provision of physician's services. Without strong constraints afforded by consumers or outside regulators, consumer welfare is guarded (perhaps not so securely) largely by professional standards of efficacy of treatment. To assess the efficacy of new treatments doctors consult with each other and apparently aim for professional consensus, guided by the judgments of certain key experts. L. Mohr's study of the spread of new practices and policies across local public health services reveals a similar "professionalism" at work. In such sectors, the screening and spreading of innovations depend in large part on these collective evaluation and information spreading mechanisms.

We hope we have persuaded you that there is considerable variation among sectors in their "selection environments" and that these differences can affect both the speed and the extent of spread of any innovation. It might be conjectured that these differences would influence the level of productivity at any time but not its rate of growth. We think this is wrong for two reasons. First, even if one assumes that the rate of advance of "best practice" is not influenced by the selection environment, it is not apparent that sectors need be characterized by a constant ratio of average to best practice. In some nonmarket sectors it is hard to identify strong forces that will prevent that ratio from falling. Second, and probably more important, the selection environment feeds back powerfully on the incentives for *R&D* by the firms in the sector. In industries like aviation there may be overstimulation. In agriculture, support of *R&D* is dependent upon suppliers or public sources of finance. Analysis of the incentives for *R&D* support by the firms in nonmarket sectors would appear to require a detailed study of operative values and sources of finance, but we would conjecture that in many cases the incentives for *R&D* support are quite weak. Thus one of the most important reasons for study of selection environments is that such analysis is necessary before one can evaluate the adequacy of prevailing *R&D* institutions.

Space limitations have forced us drastically to oversimplify and to curtail the discussion. We hope we have given at least a slight flavor of the kind of institutional richness that our proposed mode of theorizing aims to encompass. But the proof of the pudding will be in the eating.

CHINA AND INDIA: DEVELOPMENT DURING THE LAST 25 YEARS

Chinese and Indian Development: An Interdisciplinary Environmental Analysis

By BARRY RICHMAN*

This paper is based on my own firsthand research in the People's Republic of China and India during the second half of the 1960's, as well as information derived from numerous other sources. (See Richman and Richman and M. Copen, as well as the extensive documentation contained therein.) My interest here is in explaining major differences in the economic development of these two countries in terms of certain fundamental differences in their social development and underlying ideologies.

Economic development performance is reflected in such conventional indicators as gross national product and per capita income growth rates, industrial and agricultural output, etc. China has done considerably better than India in the last twenty-five years or so with regard to most indicators of economic development. (See, for example, the following works and the numerous sources cited therein: T. Weisskopf; K. I. Chen and J. S. Uppal; Richman; and Richman and Copen.)

I use the term social development here to include not only progress with regard to education and human resource development, health, welfare, social mobility, and raising real living standards, but also in connection with major changes in the attitudes, values, motivation, and behavior patterns of the population, as well as relationships between individuals, groups, and the broader society. Income distribution, which is also of major interest here, can be considered as part of economic and/or social development, although I treat it as being more a part of the latter since it tends to be more a sociological and ideological issue than an economic one.

I. Central Thesis

The central thesis of this paper is that the willingness and ability of people to work relatively hard and effectively on a national scale for goals that inspire them are perhaps the most important factors in explaining a country's economic development, and that such willingness and ability stem chiefly from a country's social development, as defined above. Moreover, ideology—or the lack of it—tends to play a fundamental underlying role in connection with the social development strategies and related performance pursued and realized by developing countries—in this particular case China and India.

My central thesis has evolved after developing and utilizing with some of my colleagues a conceptual framework of twenty-nine interrelated domestic or national environmental factors and fourteen international variables to explain significant differences in the economic development and management of different countries, including China and India. The environmental variables have been broken down into the following categories: educational; sociological-cultural (which includes psychological factors); political; legal; and economic. (See R. Farmer and Richman, Richman, and Richman and Copen.) Many of these factors are similar to the forty-one indicators of sociopolitical and economic organization and development that I. Adelman and C. T. Morris have focused on in their analysis of seventy-four countries (including India, but not China). Both their findings and ours have revealed an intimate association between the pace of economic progress and noneconomic forces relating directly to social development as defined here. This is also true of Gunnar Myrdal's massive, three-volume *Asian Drama* study.

---

* Professor of management and international business, University of California, Los Angeles.

I will focus on a number of aspects and indicators of social development which clearly seem to be associated with and highly relevant to explaining differences in the economic performance of these two countries. In fact, it appears that a good case can be made that there is a causative as well as a correlative relationship between various key aspects of social development and economic development performance. Moreover, it seems that social development strategies are often more important with regard to economic performance than economic strategies involving such things as type of economic system, resource allocation mechanisms, monetary and fiscal policies, organization of capital markets, the use of foreign assistance and resources, etc.

Before proceeding, a number of basic concepts and Western theories warrant brief comment, since they are relevant in explaining differences in Chinese and Indian development.

II. Some Basic Concepts and Relevant Theories

Harvey Liebenstein seems to have first coined the term X-efficiency and also presented evidence suggesting that other types of efficiency are often much more significant than allocative efficiency in terms of explaining economic growth and development. He has viewed motivation as being a major element in connection with X-efficiency, as well as other things, such as knowledge, information, and training. Motivation is critical in both bringing about and sustaining significant productivity or efficiency improvements and applying better methods and techniques on a broader front. Where motivation is relatively weak, there is likely to be considerably more slack in the system and hence a lesser degree of efficiency (see, for example, R. M. Cyert and J. G. March). Most human beings work at only a fraction of their overall potential in most societies, and gains from increasing X-efficiency are frequently much greater than those derived from increasing allocative efficiency.

The dominant attitude toward achievement—which relates directly to human motivation—and productive work tends to be a vital determinant of economic development (as well as social development). Studies pioneered by David McClelland and his colleagues clearly suggest that there is a rather close correlation between the achievement drive (or need for achievement) of different peoples and their countries' rates of economic growth. (See McClelland, 1961, 1963, and 1965;. McClelland and D. Winter; and Richman, pp. 281–91.) Achievement motivation is also related to social mobility, as well as attitudes toward education, training, and self-improvement.

Chester Barnard and Abraham Maslow have made pioneering contributions with regard to gaining a better understanding of human motivation by focusing on human needs and incentives. Barnard dealt with the "economy of incentives" and noted that material incentives seem to be rather ineffective positive motivators beyond the subsistence level for most people. Most human beings do not tend to work harder merely for material things, nor are they induced by material rewards to devote more than a fraction of their possible contribution at work. Barnard also considered "methods of persuasion" related to changing man's desires and attitudes with regard to human motivation, and this too is relevant to our central thesis.

Maslow presented five basic classes of human needs and placed them in a framework referred to as the hierarchy of needs. He hypothesized that, if all of a person's needs are unsatisfied at a particular time, satisfaction of the most dominant will be more pressing than the others. As fast as one set of needs is adequately satisfied, one tends to move up the hierarchy to the next set. This need-system or hierarchy is as follows, moving from the lowest to the highest level: (1) physiological; (2) safety; (3) belongingness or social needs; (4) esteem; (5) self-actualization. The last two are essentially psychological in nature.

More recent behavioral research by others has demonstrated more convincingly that material incentives tend to serve as necessary but frequently not sufficient conditions for productivity growth and efficiency over time. (See Richman and Farmer, especially chapters 14–16, and the sources cited in the bibliography.) Some job conditions may serve primarily to dissatisfy personnel, such as insufficient income, lack of job security, or poor working conditions. Yet improving these conditions often does not build strong motivation or contribute to significantly more effective and efficient performance. Social and psychological need-fulfillment tends to be more important in this regard.

Effective leadership and management over time usually involves having a good grasp of what results in individual and group satisfaction and dissatisfaction and how this relates to human motivation, behavior, and performance. Furthermore, truly effective and durable leaders and managers are usually perceived as being able to facilitate in significant ways the satisfaction of the personal needs and the attainment of the personal goals of their followers.

III. Ideology, Leadership, and Development

Ideologically and on the social front, China's basic aim has been to bring about a fundamental transformation of society, involving all of its social and economic institutions as well as the values, attitudes, motivation, and behavior patterns of its people. China's leadership has desired and striven for a collective egalitarian social system, a society without much of an individualistic orientation and with essentially public ownership of resources and capital assets—a nation of classless, cooperative, and altruistic citizens dedicated to the betterment of the broader society. And although Chinese society is still far from the ideal visualized by the more ardent Maoists, it is probably closer to this ideal than any other Communist country.

India's political leadership has sought to bring about major changes in traditional Indian society—and has been far less effective than China's leadership in this regard—but it has not rejected Western liberal values of individual freedom and private property rights. This involves a form of social democracy in which efforts are made to assure equal rights and social justice within the context of essentially bourgeois social, political, and economic institutions and to some extent within a mixed economy framework. In general, India is much further from its idealized society, and its ideology has been much more ambiguous and far less effective with regard to social change and overall development than has been the case in China.

The fundamental ideological differences of these two countries, and particularly how effectively their ideologies have been implemented, can explain much about the development strategies pursued by them and particularly about basic differences in social development which, in turn, relate to differences in economic development. For ideological reasons, China's leadership has pursued social development as an end in itself, rather than merely as a means to economic development, much more vigorously and effectively than India. As a consequence this has contributed much to China's superior economic performance.

Communist Chinese ideology consists of both the pure ideology of Marxism-Leninism and the practical ideology based on the "Thought" of Mao (see F. Schurmann for an excellent study of Chinese ideology). Pure ideology is viewed as theory based on universal truths dealing with values and ethics, and at its core is Marx's thesis of class struggle. It essentially involves a set of ideas designed to give the individual a unified and conscious view of the world. Practical ideology states norms and rules which prescribe behavior and have action consequences, but such ideology must be interpreted concretely to be operational. The Thought of Mao is a process of combining pure ideology or universal truths with concrete practice—practical ideology cannot be used until one has worked out correct thought, which does not simply mean a certain manner of thinking developed through intensive study, but also a manner of actually behaving. This approach has proven to be a very effective "method of persuasion" in China.

It is worth commenting briefly on a few of Mao's works that are most commonly studied and discussed in China. "On Contradictions" is studied in order to provide people with a "correct" and scientific view of reality and to help them in solving problems and overcoming obstacles. They are encouraged to persist in working out problems even where seemingly conflicting or incompatible factors are involved (e.g., raising product quality and reducing production costs simultaneously). "On Practice" is aimed at getting people to behave according to correct ideological standards through constant practice, experience, and evaluation. Another aim is to merge theory —including nonideological theories ranging from physics and engineering to bookkeeping and operating machines—with practice and application. Here, too, overcoming obstacles, problem solving, and persistence are stressed as well as self-improvement and better performance. "In Memory of Norman Bethune"—who was a Canadian surgeon who served with the Red Chinese Army in the field in the 1930's and died there—extols Bethune's virtues of selflessness, response to moral stimuli, altruistic dedication to his fellow man, classlessness, and humility. This work is studied with the aim of reducing the importance of self-interest and material gain as key motivating forces and of illustrating the value and correctness of a classless society mentality.

When the study of Mao's and other ideological works have not been carried to the extreme in China, they have undoubtedly had a major positive impact on China's social and economic development performance. China's party leadership has capitalized on, modified, created, and put into widespread application attitudes and values that are conducive to economic development—such as nationalism, the desire for achievement, work motivation, pride, dedication, loyalty, self-improvement, self-confidence, cooperation, resourcefulness, thriftiness, a more scientific view of the world among the masses, and so on. They have put these human forces into productive operation on a national scale through effective and persuasive—and at times outright coercive—political leadership, management, mobilization, and organization at both the macro and micro levels of society. The regime has relied on and effectively utilized the country's overall educational and training system, mass media, and entertainment and recreation of all types, as well as intensive study, indoctrination, discussion, self-criticism, and appraisal at all levels of society, typically under the direction of party or other ideological cadres.

In India, the shaping of an overall social environment conducive to more rapid and sustained economic development has been a far slower and much less effective process. This has been largely due to the lack of an effective underlying ideology, especially in terms of implementation, as well as the lack of effective political leadership, management, organization, motivation, and mobilization that are essential at both the macro and micro levels of society for major and basic social change on a national scale.

IV. Social Development Performance

The previous section focused on the importance of ideology with regard to development generally. At this point we shall examine a number of key aspects of Chinese and Indian social development performance which tend to support the central thesis of this paper.

A. Education and Human Resource Development

There tends to be a close correlation between a country's overall literacy rate and its level of economic development. The literacy rate is both a cause and result of development, and in a poor nation it seems to be one of the prime factors influencing development. In 1950 less than 10 percent of the Chinese population was literate compared to about 16 percent of India. In the 1970's about 50 percent of China's population is literate compared to less than 35 percent in India. Much of China's superior literacy performance is attributable to spare-time adult literacy programs, which have been relatively uncommon in India. (This section is based largely on data presented in Richman, ch. 3; Richman and Copen, ch. 3; and M. Blaugh, R. Layard, and M. Woodhall.)

In recent times roughly 40 percent more of China's population of primary school age has been enrolled in elementary schools than in India, and a much higher proportion has completed primary education in China. China has also provided a considerable amount of adult part-time primary educational programs, while India has had relatively few. The same has been true with regard to secondary education of all types. China also seems to have done a more effective job in imparting knowledge, skills, values, and attitudes in both primary and secondary education which are more conducive to economic development.

A significantly larger proportion of China's youths have been enrolled in and graduated from junior high school in recent times than in India. India has had a higher proportion in regular or general senior high schools, but the gap has been narrowing steadily. There has been much more stress in China's overall secondary educational system on technological, industrial, applied science, and agricultural training and on applied and practical education generally.

A major source of skilled and semiprofessional manpower for the Chinese economy is its system of specialized secondary and vocational training schools; and many of these also have part-time adult programs. India's overall system of this type lags far behind China in terms of enrollments, graduates, and probably also the quality and effectiveness of the instruction.

India has had larger enrollments and more graduates—in both total and per capita terms—in its overall system of higher education, but the overall growth of Chinese higher education has been significantly greater—with the notable exception of the Cultural Revolution period. China has also had much more part-time higher education and far fewer higher graduates unemployed than India. China has a substantial lead in technological, industrial, agricultural, and health fields and in the applied sciences—roughly twice as many students percentagewise have graduated in such fields in China compared to India in the past twenty-five years or so. India is significantly ahead quantitatively, and possibly also qualitatively, in the liberal arts, humanities, and the social sciences, though here too the gap has been narrowing steadily.

Hence, only in regular senior secondary and overall higher education have India's enrollment figures exceeded those of China. But this seems to clearly underline the relatively top-heavy structure of the Indian general educational system, which provides disproportionately great opportunities to those who have the resources to continue their education while at the same time limiting access considerably more than China to the bottom of the educational ladder.

Given the generally more favorable attitude toward practical and applied education in China, industrial, agricultural, and other personnel are more inclined to want to improve their skills, abilities, and performance through on-the-job training, self-education, and self-development, as well as through formal education, than in India. This has also been spurred on by the existence of many more opportunities for individual advancement in China.

B. Motivation

Two meaningful quantitative indicators of work motivation are labor productivity and absenteeism. The evidence available indicates that China has had significantly higher labor productivity in its economy generally and dramatically less personnel absenteeism as compared to India. (See Richman, pp. 260–61, 316, 514, 646–53, and 838–69; and Richman and Copen, pp. 532–35 and 590–91.) Some of the apparent important reasons for more effective human motivation overall in China as compared to India have already been noted. Here we shall elaborate and go into greater depth.

China clearly seems to have done a much more effective job of raising and capitalizing on the achievement drive of its population. China has succeeded in markedly raising the aspiration levels of its population in a variety of ways: formal education and training; effective ideological programs and campaigns, bringing about changes in child-rearing practices which are related to the breakdown and reorientation of the traditional family structure; and providing for greater educational and career opportunities generally. India has been considerably less effective overall.

India lacks a practical ideology of the Chinese type which transmits in standardized language concern with achievement on a continued basis to the studying and working population; and there has been no monolithic or effective political organization like the Chinese Communist Party which constantly stresses achievement and the virtues of hard work at the grass roots levels of society. Moreover, opportunities for upward social mobility and career advancement have generally been substantially more limited in India; this has been due largely to the class or social structure and slower rates of economic growth and expansion.

The fulfillment of social and psychological needs appears to have been emphasized to a much greater degree and extent and evidently with significantly greater effectiveness in China. Moreover, the physiological and safety needs of the common citizen have also probably been fulfilled to a significantly higher degree and extent. Apart from periods of ideological extremism, monetary incentives and personal gain have not been vigorously suppressed, but they have been restricted in their quantitative scope and supplemented by greater stress on moral stimuli, social and psychological need-fulfillment, and other incentives linked to a more egalitarian system of control over economic activity at the micro level. In other words, China seems to have been more effective in applying what Barnard has called "the economy of incentives," and this has resulted in more financial and other resources being available and used for reinvestment, economic expansion, and capital formation.

Three aspects of social development which are closely related to motivation warrant further attention: social mobility; income distribution; and participation.

C. *Social Mobility*

Educational and career opportunities are two of the most important indicators of social mobility in a country or society. The proportions of students from worker and peasant origins—and those who have actually been workers and peasants themselves—in Chinese secondary and higher education have increased very dramatically since 1949 and have comprised a significant majority of the overall student population at both levels for about fifteen years (Richman, pp. 297–98; and Richman and Copen, pp. 88–91). At the same time, except during periods of ideological extremism, students from less humble family backgrounds have also received higher educations in numbers equal to or greater than their proportionate representation in society. India's secondary and higher educational systems have been dramatically more elitist with regard to their student populations. As compared to China, vastly fewer students have been from worker and peasant families. This has no doubt contributed to a significantly greater willingness and ability for more people to work hard and effectively in China as compared to India.

My own study of the class origin of key personnel in a sample of thirty-eight Chinese industrial enterprises revealed that a substantial majority of such personnel were from worker and poor and middle peasant backgrounds (Richman, pp. 295–306). There have been many opportunities for individual advancement in Chinese industry and few barriers to promotion at most levels on the basis of ability—except during periods of ideological extremism when those from more traditionally elitist backgrounds have tended to be discriminated against, at least to some extent.

By contrast, studies of social structure in India underline the continuing significance of class and caste in limiting mobility and structuring the occupational hierarchy (N. Nijhawan; Richman, pp. 307–09; Richman and Copen, pp. 152–56; and the sources cited therein). Heredity, nepotism, family wealth and status, the "right social background" and "proper connections" have continued to play a large and pervasive role in determining opportunities for advancement in India. The vast differences in social mobility in connection with career advancement probably also contribute to the willingness and ability of a significantly greater proportion of China's population to work hard and effectively as compared to India.

D. *Income Distribution*

In India there has been little or no reduction in the highly unequal distribution that characterized that country at independence, and it is possible that the degree of income inequality has actually increased. (See Weisskopf, pp. 8–13, and the sources cited therein.) By contrast, China has been remarkably successful in narrowing income inequalities and thereby assuring a certain minimum standard to most if not all elements of the population.

My own survey of Chinese enterprises revealed that the ratio of top pay to average pay was typically no greater than 2.5 to 1. The highest ratio was 4 to 1. At most enterprises the differences between top and lowest pay was less than 4 to 1, and the highest paid employee in the entire sample received only about seven times more than the lowest paid. High-level company and plant managers in India often receive net incomes twenty or thirty times greater than the average worker (Richman, pp. 798–809). Moreover, the dramatic contrast between pay differentials in India and China actually understates the differences in the range of employee living standards. For in China many goods and services are provided more or less equally to all employees at highly subsidized rates. On the other hand, in India higher level executives often enjoy various job perquisites that are unavailable to lower level employees. Here the inequality in real income exceeds the inequality in money incomes.

The much greater income equality in China has served to satisfy human physiological and safety needs to a far greater extent than in India, and this has undoubtedly resulted in greater willingness and ability among many more people in China to work hard and effectively. It has also enabled greater and more effective use of moral stimuli and incentives linked to social and psychological need-satisfaction.

China's much more egalitarian strategy does call for greater diversion of resources from other uses to benefit the poor, and it may involve some dampening of individual material incentive gains. However, gains from such a strategy in terms of economic development in a poor country like China clearly seem to have outweighed the losses for reasons already noted. Greater equality in consumption can also contribute directly to improved worker health and productivity. Moreover, greater equality in income distribution can help limit wasteful consumption and the demand for scarce factors of production such as capital and foreign exchange (see Weisskopf, pp. 26–27).

E. *Participation*

China has emphasized employee participation in the management, planning, and decision making of organizations. A basic aim here, too, has been to bring about a more egalitarian society by reducing hierarchical and role distinctions. When not pushed too far too quickly, such participation has evidently contributed positively to the wllingness and ability of more people to work harder and more effectively. (See Richman, especially pp. 253–61.)

Employee participation can have positive effects with regard to the satisfaction of social and psychological needs. It can result in a greater sense of identification with and loyalty, belonging, and commitment to the organization. It can contribute to more effective education, training, communication, and information dissemination and feedback, since employees down the line analyze plans, problems, and results, exert initiative, and make suggestions for improving performance. Managers up the line can gain a better insight into the capabilities, attitudes, and opinions of lower level employees.

The degree and extent of employee participation in Indian productive organizations generally have been very minimal as compared to China. In general, Indian organizations typically utilize traditional hierarchical structures and authoritarian forms of management. There is also typically less decentralization or delegation of authority and much less voluntary cooperation, mutual assistance, and sharing of information in India as compared to Chinese organizations. (See Richman and Copen, chs. 4, 13, and 14.)

F. Health

Health is a very important factor in connection with the willingness and ability of people to work hard and effectively. Both India and China have made considerable strides in medicine and health care in the last twenty-five years or so. However, China's progress has been more rapid and effective, and China has been far more successful in spreading the benefits of improved health care throughout all levels of the population. (See R. Quinn; M. Wegman, T. Y. Lin, and E. Purcell; and Richman, pp. 538–40 and 551–55; and the sources cited therein.)

The much more equitable distribution and consumption of food in China also have a significant bearing on health. Even in absolute terms, China's per capita caloric food intake has been higher in recent times, and most people in China probably have had a more balanced and nutritious diet as compared to India.

V. Ideological Extremism and Chinese Development

References have been made at several points to ideological extremism in China, and some elaboration is in order here. Ideology has played a vital role with regard to China's impressive development; but when ideology has been pushed to extremes—in terms of economic, technical, and managerial feasibility or rationality—it has led to very serious economic (as well as political and social) crises (see Richman).

Thus far there have been two major periods which can be characterized as ones of ideological extremism in China. They were the Great Leap Forward of 1958–60, and the Great Proletarian Cultural Revolution of 1966–69. A basic ideological aim of both was to create rapidly a nation of dedicated and pure communist citizens as defined and perceived by Mao, or at least as defined in his name. This involves a nonbureaucratic society of selfless, altruistic, classless, and equal people.

During these two periods, the regime pursued vigorous campaigns, programs, policies, and practices with the aim of eliminating significant differences in the roles, status, privileges, material benefits, and living standards of leaders and followers, superiors and subordinates, managers and workers, generalists and specialists, party officials and the masses, the well-educated and the poorly educated, mental and physical labor, and so forth. A vigorous effort was also undertaken to replace material or monetary incentives and self-interest as key motivating forces with moral stimuli and appeals to altruism and self-sacrifice for the sake of the collective and the state. All of this had pervasive negative effects with regard to human motivation and need-fulfillment, as well as the effective utilization of knowledge and skills.

In an effort to implement the above programs the regime sought to have Reds (ideological purists) take over operating management and leadership functions normally performed by the experts (e.g., professional managers and administrators, engineers, scientists, technicians, staff specialists, etc.), because it was believed that the latter could not be counted on to implement such programs. When the Reds have taken over in this manner, ideology and politics have tended to take precedence over managerial, technical, and economic feasibility or rationality when a choice has had to be made—which typically has been frequently. Ideological indoctrination and political education sessions also became greatly intensified throughout the society—both during and after working hours. This too greatly constrained and inhibited the willingness and ability of people to work hard and effectively on a national scale.

It should be emphasized, however, that even during more normal periods of relative ideological moderation—and this has been most of this time since the Communists came to power in 1949—China has probably been the purest communist country in a relative—but by no means absolute—context. As already discussed, emphasis on ideology has had major and pervasive positive impacts on China's overall development.

VI. Conclusion

China has done considerably better with regard to both economic and social development than India has to date; and China has gone much further in creating an overall social environment conducive to sustained and substantial economic growth and development in the future. The apparent significantly greater willingness and ability of the Chinese people to work hard and effectively on a national scale for goals which inspire them may well be the most important factor in explaining China's superior economic development performance. Such willingness and ability stem chiefly from basic differences in the social development of the two countries, and ideology in conjunction with effective leadership clearly seems to have played the fundamental underlying role in this regard.

However, there appears to be an inherent conflict between the pure ideological goals and the ultimate economic, materialistic, and power objectives that Mao and his ardent supporters desire to implement and achieve: if China does evolve into a truly advanced economy, it would seem that some of the more important aspects of pure Maoist-Marxist-Leninist ideology would have to be compromised considerably in the process.

It is conceptually possible that the Chinese Maoists may have discovered a magic or spiritual tool which no other country has come upon. They may have a key which will allow ideology not only to create a pure philosophical state in reality but also develop a leading world productive system at the same time. To date, the available evidence indicates that the chances of this coming to pass are remote.

My own bet would be on some tradeoff between ideological aims and economic growth and development by China's current and future leadership. China may well be able to continue to be the purest communist state in existence—at least as conceived by the Maoists, though certainly not pure in the ultimate sense—and simultaneously achieve respectable and possibly even impressive economic growth and overall development over time. Unfortunately, the outlook for India's future development does not look nearly so bright at this time.

China and India: Contrasting Experiences in Economic Development

By THOMAS E. WEISSKOPF*

Any effort to compare the development experiences of modern China and India must confront the fact that the development objectives of the political leadership of the two countries have differed in important ways. The Chinese Communist Party has clearly been aiming to bring about a fundamental transformation of Chinese society, involving all of its social and economic institutions as well as the attitudes and behavior patterns of the Chinese people. There have been internal differences over the extent and the pace of the change, but the overriding goal of the Chinese leadership has been to build a socialist—and ultimately a communist—society that rejects the individualistic orientation of most contemporary societies in favor of a collective and egalitarian social system. The Indian political leadership has sought to bring about major changes in traditional Indian society, but it has not rejected the Western liberal values of individual freedom and property rights. Instead, the Indian sociopolitical goals may fairly be summarized as the establishment of a form of social democracy, in which efforts are made to assure equal opportunity (but not equal outcomes) in the context of bourgeois political and economic institutions.

Within the framework of these overriding social objectives, there are three broad economic objectives that have been shared by both nations: rapid economic growth, greater economic equity, and greater economic self-reliance. I define economic equity to include not only an equitable distribution of income but also the provision of employment opportunities and basic social services for everyone. By economic self-reliance I mean the ability of nationals of a country—rather than foreigners—to make decisions that affect economic activity within the country.

I believe that on the whole the Chinese have been considerably more successful than the Indians in achieving the basic social goals of their development efforts. In many important ways the Chinese have succeeded in establishing more collective and egalitarian institutions and practices. India has maintained a parliamentary democracy and civil liberties to a degree that is exceptional among contemporary poor countries; but equal rights and social justice remain distant ideals. Unfortunately, such noneconomic aspects of development do not lend themselves readily to systematic comparison and evaluation. In the remainder of this paper I will therefore (reluctantly) confine my attention to the economic sphere of development.

My topic remains an extremely broad one, and I can only hope to provide a very cursory survey here. In Section I I will assess the progress of modern China and India with respect to the three broad economic objectives of development. In Section II I will contrast the Chinese and Indian approaches to development, and in Section III I will attempt to relate the differential progress of the two nations to differences in their basic approaches. I will conclude in Section IV with some observations about the underlying reasons for the differences in the development experiences of modern China and India.

---

* Associate professor of economics, University of Michigan. In writing this paper I have drawn both upon personal experience (four years of teaching and research in India in the 1960's and a brief visit to China in 1972) and upon the extensive professional literature on modern India and China. Rather than burden the text with continual footnotes and references, I have simply included the most important of my bibliographical sources in the list of references. The Twentieth Century Fund assisted in financing the research for this work; I am indebted also to the Center for Research on Economic Development at the University of Michigan for the use of its facilities.

I. Economic Development Progress

I have presented elsewhere (see Weisskopf 1974) a systematic and fully documented comparison of China's and India's economic progress in the modern postwar period. Here I will simply summarize the results of that study.

A. *Economic Growth*

The record of economic growth has unquestionably been better in China than in India. Most estimates of the average annual rate of growth of real output in China from 1952 (after an initial period of recovery) to the early 1970's range between 4 and 6 percent. The corresponding figure for India, based on official estimates, is 3½ percent. With population growing at about 2 percent per year in each country, the average annual rate of growth of *per capita* output has probably been twice as high in China (2–4 percent) as in India (1–1½ percent).

These long-term growth rates conceal considerable variation during the period under consideration. Of greatest current significance is the fact that since the mid-1960's the Chinese rate of growth has exceeded its two-decade average, while the Indian rate has been below the two-decade average. Moreover, in the past few years (beyond the range of the growth figures) there is evidence that the Chinese economy has fared much better than the Indian economy.

The more rapid growth of the Chinese economy from the early 1950's to the early 1970's was attributable primarily to the exceptionally rapid growth of Chinese industry. Chinese industrial growth averaged from 8–12 percent per year as opposed to 6 percent in India. On the other hand, Chinese agricultural growth may have been slightly less than that of India, averaging 2–3 percent per year as compared to roughly 3 percent in India. Once again, however, figures from the mid-1960's to the early 1970's and qualitative reports of more recent developments suggest that China's relative performance has improved in the past decade.

B. *Economic Equity*

It is in the area of equity that China's achievements have probably been the most impressive of all. Although there are no comprehensive data on the size distribution of income in China, all of the qualitative and fragmentary evidence suggests that there has been a vast redistribution of income from rich to poor since Liberation. My reading of the substantial (but often conflicting) quantitative information from India suggests that at best there has been no reduction in the highly unequal size distribution of income that characterized India at Independence, and most probably the degree of income inequality has increased. Limited evidence on urban-rural and interregional differentials in economic well-being suggest that both China and India may have narrowed some of the disparities, but that the improvement has most likely been greater in China than in India.

There can be no doubt that with respect to intraenterprise income differentials China has become vastly more egalitarian than India. Chinese differentials—in real terms—are probably the lowest in the world. In the provision of such basic social services as health care, literacy, and primary education, China's performance is also widely recognized as more successful than India's. India has made great strides in medicine and education, but China has made more progress in spreading the benefits of improved health care and education throughout all levels of the population.

Both China and India began their development efforts with a large burden of underemployment and unemployment. Unfortunately, there are formidable conceptual and empirical problems which make it very difficult to compare the changing employment situations in the two countries. The necessarily fragmentary information available points to the following tentative conclusions: (1) in urban areas overt unemployment is a much more serious problem in India than in China, for China has been more successful in absorbing labor into industrial and service activities (even if in relatively unproductive roles); (2) in rural areas underemployment remains a problem in both countries, but China's communal organization has been more effective in mobilizing rural labor and reducing the degree of underemployment than India's private farms and public agencies. Whatever the relative gravity of the problem of unemployment in China and India, there can be little doubt that China has managed much more successfully to provide the basic necessities of life to its economically marginal population.

C. *Economic Self-Reliance*

Although it is difficult to measure self-reliance directly, there are several indicators which are clearly relevant to its attainment. The most obvious of these is the extent of national control over productive assets. Since the early 1950's there has been no foreign ownership or control of economic activity in China. In India a substantial fraction of the modern corporate business sector (probably between 25 and 50 percent) is directly or indirectly under foreign control.

A second significant indicator of economic self-reliance is the extent to which a country is free of foreign debt. China received loans from the Soviet Union in the 1950's but repaid all of them by the early 1960's. Since then, China has maintained a generally favorable balance of payments and has remained free of any major foreign indebtedness. India has been plagued by a more or less continual foreign exchange crisis ever since the late 1950's and has had to make use of large amounts of foreign aid and loans to meet its balance of payments problems. As a result, India has found itself in a position of increasing indebtedness to the Western capitalist nations who have provided most of the capital inflow.

A final important indicator of economic self-reliance is the extent to which a country has developed an independent technological base for economic activity. This is inherently difficult to evaluate, but reports from qualified observers tend to agree that China is ahead of India in its overall technological capacity and particularly in its indigenous technological base. All in all, the evidence points clearly to the emergence of modern China as an economically more self-reliant nation than modern India.

II. Approaches to Economic Development

In both China and India there have been policy disputes and policy changes during the past quarter century, but the fundamental character of the approach to development in each country has remained fairly consistent over time. In this section I will briefly focus on some of the key differences in the Chinese and Indian approaches, as reflected in their basic economic institutions and overall development strategies.

A. *Economic Institutions*

The Chinese have systematically sought to minimize the role of private enterprise; they have relied almost entirely on public initiative and collective enterprise to spur economic development. Although various forms of private economic activity were tolerated during a period of transition in the 1950's, the pattern since the late 1950's has involved predominantly public control of both agricultural and nonagricultural activities. India has maintained a constitutional guarantee of private property rights and has accorded a predominant role to private enterprise in development. The Indian public sector has grown rapidly and includes many important modern industrial enterprises, but it still accounts for only a small portion of all nonagricultural activity and virtually no agricultural activity.

The Chinese economy is far more thoroughly planned than the Indian economy. Use of the market mechanism has varied over time and by sector, but resource mobilization and allocation have always been determined to a large extent by administrative means at various levels of the Chinese administrative hierarchy. In India, planning has in practice meant not replacement of the market mechanism but efforts to control it, either through expansion of government-controlled enterprise or through various forms of quantitative controls (e.g., investment licenses or foreign exchange allocations). Like private enterprise, the market has remained dominant in India, but it has had to contend with a great variety of interventions, restrictions, and distortions introduced by the government in its effort to gain some control over the economy.

In China serious efforts have been made to depart from the conventional mode of work organization, which involves a very hierarchical structure of authority within each enterprise and the use of individual gain incentives as a prime incentive to work. Although the Chinese experience shows periodic advances and retreats in this regard, individual gain incentives have been restricted in their scope and supplemented by collective incentives linked to a more egalitarian structure of control over economic activity at the micro level. In India no serious departure from the conventional mode of work organization has been contemplated in either the public or the private sector.

B. *Development Strategies*

Both the Chinese and the Indian political leaderships initially stressed the importance of institutional change for economic development, especially in the context of their predominantly traditional agrarian societies. In practice, however, the Chinese strategy has involved a much greater emphasis on institutional change. In progressing from early land redistribution to the ultimate collectivization of agriculture under a system of communes, the Chinese thoroughly transformed the character of their rural society. Indian efforts at land reform and "community development" have had much less impact on traditional agrarian social and economic relations. Disappointment with the pace of agricultural progress in both China and India led to a greater emphasis on technological change in agriculture beginning in the early 1960's. But in China the process of technological modernization has been linked to a new policy of rural industrialization, while in India it has been pursued without any major change in rural institutions.

In China the government—at various levels—has made a much more substantial effort to mobilize labor than in India. Apart from periodic mass campaigns engaging large numbers of workers in collective projects, the Chinese have systematically sought to organize communes, factories, neighborhoods, etc., so as to maximize employment opportunities. In India there has been some government subsidization of labor-intensive handicraft industries. But very few resources—financial or organizational—have been committed to large-scale public works projects or other employment-promoting activities.

The Chinese development strategy has placed a much greater emphasis on the welfare of the poor than the Indian strategy. Collective organizations developed in urban and rural areas in China have been designed to bring virtually everyone into a network of mutual social responsibility, whereas in India many people remain beyond the reach of public agencies and dependent on private charity.

Although in both countries the role of foreigners has varied over time, India's development strategy has on the whole accorded a much larger role to foreigners than China's strategy. Foreign private investment in China was liquidated soon after Liberation. The Indian Government has often spoken in economically nationalist terms, but it has in fact permitted a rapid growth of foreign private investment since Independence. China received economic and technical assistance from the Soviet Union in the 1950's, but since then has done without any net capital inflow and with only a very limited amount of (non-Soviet) foreign technical assistance. India received modest amounts of economic aid and technical assistance in the 1950's, but since the foreign exchange crisis of the late 1950's India has utilized a far greater amount of aid than China ever did. Throughout the 1960's foreign capital inflows—as well as foreign economic agencies—played a crucial role in India's development efforts.

III. Sources of Differential Progress

To what extent can China's greater progress in economic development be attributed to differences in the Chinese and Indian approaches to development, as opposed to differences in circumstances beyond the control of economic policymakers? With respect to the objectives of economic equity and self-reliance, differences in approach have clearly played a major role.

The greater success of the Chinese in overcoming inequalities and unemployment can be attributed in considerable part to the character of the basic economic institutions and development strategy espoused by the Chinese. First, the elimination of virtually all forms of individual private property in China removed the biggest source of income inequality. In India continued respect for private property rights has resulted in the perpetuation of enormous inequalities based on differential private holdings of land and capital assets. Second, the greater degree of centralized public control over resource allocation and lesser reliance on the market mechanism in China have permitted (but of course not necessitated) a more equitable allocation of resources among income classes and regions than has been possible in India, for the unimpeded operation of private enterprise in a market context tends to perpetuate—if not to exacerbate—initial inequalities. The deliberate Chinese emphasis on promoting the welfare of the poor and an institutional framework permitting major redistributive programs to be implemented have contrasted sharply with the somewhat sporadic concern for the poor shown by the Indian Government (depending on current political pressures) and an institutional framework rendering implementation of redistributive efforts very difficult. An additional aspect of the Chinese approach that has contributed to greater economic equity is the effort to limit the scope of individual material gain incentives; this has allowed for reductions in labor income differentials at the enterprise level to a degree inconceivable in India. Finally, the greater stress on the mobilization of labor in the Chinese approach—facilitated by an institutional framework involving strong public control over the labor market—has enabled China to combat unemployment and underemployment more successfully than India.

China's greater success in promoting economic self-reliance has resulted largely from deliberate strategic choices of the Chinese leadership. As a matter of policy, the Chinese decided to eliminate foreign investment while the Indians ultimately encouraged it in many areas. The Chinese deliberately pursued conservative international financial policies to avoid long-term indebtedness after the 1960's, while India welcomed large amounts of aid and loans which resulted in increasing debt. The Chinese allocated more resources and effort to the development of indigenous technological capacity, while the Indians relied to a much greater extent on the foreign technology introduced by foreign private enterprise. The termination of Soviet aid to China in the late 1950's and the lack of aid opportunities from other sources may have given an extra exogenous stimulus to Chinese efforts that India did not have. But in principle the Indian Government could have generated the same stimulus to self-reliance (at some possible cost in economic growth) by choosing as a matter of deliberate policy to curtail its utilization of foreign aid.

In the case of economic growth it is not so obvious that differences in the Chinese and Indian approaches to development are responsible for the differential performance. It is conceivable that uncontrollable differences—e.g., in cultural heritage, in ethnological structure, in initial economic conditions, in natural or external events—may have favored more rapid growth in China than in India. However, I believe that there are several important respects in which the Chinese approach to development has been more conducive to economic growth than the Indian approach.

First of all, the Chinese approach has involved a much more radical transformation of social and economic institutions than the Indian approach. In virtually all spheres of society the Chinese have brought about fundamental changes that must have profoundly affected the values, attitudes, and behavior patterns of the Chinese people. In many cases the institutional changes may have been so rapid or so unsettling as to be economically counterproductive, at least in the short run. Periodic changes and even reversals of policy suggest that this has often been true. But the radical institutional changes brought about in China seem most likely to have had the long-run effect of creating a social and psychological environment far more conducive to economic and technological progress than existed in prerevolutionary China or than exists in contemporary India. With the help of a strong governmental and party apparatus and a revolutionary ideology, the Chinese leadership has managed to reach virtually all of the people and to organize and motivate them to economic achievement. In India the scope of institutional change has been rather limited and—as a consequence—the plans and the policies of the Indian Government have had relatively little impact on the lives and the attitudes of the vast majority of the Indian people.

A second major aspect of the Chinese approach to development contributing to the relatively impressive growth performance of modern China has been the strong control over the economy exercised by central authorities. The dominant position of state planners in China contrasts with a complex diffusion of power in India among government planners, private businesses, and various other interest groups. Although the Chinese Government has moved in the direction of increasing decentralization of economic decision making within the overall administrative framework, the central planners have always been able to ensure a high rate of surplus mobilization and utilization for developmental purposes. Luxury consumption has been virtually prohibited, and most consumption has been kept within essential and productive forms—i.e., consumption that improves the health, education, and general productivity of the labor force. Indian economic policy has been marked by conflict and compromise among competing interests, with no single group exercising decisive authority. On the one hand, powerful private groups have prevented Indian planners from limiting nonessential and unproductive consumption and from raising public resources and allocating them for development purposes in the amount and direction desired. On the other hand, political pressures from middle-income classes have periodically limited the responsiveness of Indian Government policy to big business interests and brought it into conflict with the desire of domestic and foreign capitalists for relatively unfettered profit-motivated expansion. The end result has been an economic strategy involving a mixture of public and private authority that has interfered with both socialist and capitalist accumulation.

The third characteristic of the Chinese approach to development that would appear to have favored faster economic growth than India's is its greater egalitarianism. No doubt an egalitarian strategy does call for the diversion of resources and energies from other areas to benefit the poor, and it may involve some dampening of individual economic gain incentives. But there are also many respects in which more equality can be functional for growth, and these respects appear especially likely to dominate in very poor and initially very unequal societies such as those of China and India. First, greater equality in consumption can contribute directly to improved worker health and productivity. Second, a more equal economic environment is likely to increase the work motivation of the labor force—particularly in the case of public works projects employing surplus labor. Finally, greater equality in income distribution may help to limit wasteful consumption and the demand for scarce factors of production such as capital and foreign exchange.

There are some respects in which the Indian approach may have been more favorable to growth than the Chinese approach. As noted earlier, India has made much greater use of foreign aid, investment, and technology than China. This has probably contributed to faster economic growth in the short run, although it is arguable that in the long run extensive utilization of foreign resources may be counterproductive because—among other things—it can inhibit the development of indigenous capabilities. The greater role accorded to the market mechanism in the Indian approach might also be considered a source of greater efficiency and hence more rapid growth in India than in China. However, the Indians as well as the Chinese have interfered in many ways with the operation of their internal and external markets. And—neoclassical orthodoxy notwithstanding—it is doubtful that pure allocational efficiency really has a significant impact on economic growth in poor countries such as China and India.

In sum, neither the Chinese nor the Indian approach to development can be considered optimal with respect to the achievement of rapid economic growth. Yet the Chinese approach appears to have been significantly more conducive to growth as well as to equity and to self-reliance than the Indian approach.

IV. Conclusion

Underlying the differing Chinese and Indian approaches to development are significant differences in the political-economic conditions that have characterized China since Liberation and India since Independence. The most crucial of these differences seem to me to involve the distribution of political power and the authority of the political leadership.

In India the attainment of Independence brought about no major redistribution of power between previously dominant and dominated classes. There was some shift of power among elites: indigenous businessmen and professionals gained at the expense of their foreign counterparts, and some of the more enterprising large landholders gained at the expense of traditional rural potentates and absentee landlords most closely linked to the British. India's parliamentary democratic system has enabled certain intermediate groups—such as moderately well-to-do peasants and organized urban workers—to have some voice in national affairs, but the vast majority of poor peasants, landless laborers, and unorganized urban dwellers remain as powerless as ever before. In China, by contrast, a truly revolutionary redistribution of power did occur as a result of the Communist Liberation. All of the old privileged classes—foreign and domestic, urban and rural—saw their power sharply curtailed (if not totally eliminated) as the Chinese Communist Party took full control of the nation. The extent to which the previously oppressed classes are now able to exercise real power is a matter of much controversy. But it is significant that the political leadership is fully committed ideologically to the supremacy of workers and peasants, and that failure to act in their interest would entail a heavy political—and probably economic—cost.

In India the capacity of the national political leadership for decisive government action is limited by several important political and institutional factors. First of all, the system of parliamentary democracy—for all its inability to equalize the distribution of political power—does permit certain interests to mount opposition to various aspects of government policy and thus to constrain the role of the central government. Second, the federal structure of government in India (in part the result of India's ethnological heterogeneity) allocates certain critical responsibilities to state governments and thereby weakens the power of the central government and the national political leadership. Third, the extensive protection of private property rights guaranteed by the Indian constitution (reflecting the interests of powerful propertied classes) sets strict limits on the authority of the state to bring about institutional changes affecting private property. Again, the contrast with China is striking. The Chinese political leadership has the authority and the capacity to exercise decisive control over Chinese society and economy. Through well-organized structures of party, army, and civilian administration, the Chinese leadership is able to implement its chosen policies with far greater effectiveness and thoroughness than the Indian leadership.

It is easy to see how the differing distributions of political power and the differing degrees of central authority have led to most of the differences in the Chinese and Indian approaches to development. In India the strength of private propertied classes has limited the role of the public sector; the weakness of central government authority has impeded the capacity for national planning; the very unequal distribution of power has inhibited the implementation of radical social change and egalitarian policies; and the limited capacity of a weak central government to mobilize the economic surplus, together with the continuing strength of private capital, has led to a considerable role for foreigners in India's development. In China, the elimination of the formerly privileged classes and the authority of the new leadership have made possible radical changes in social and economic institutions, involving a dominant role for public and collective enterprise and the effective implementation of egalitarian and nationalist policies.

A review of the political economy of the development experiences of China and India suggests that India has been paying not just the price of democracy (in a weakened central authority) but also the price of capitalism (in an inegalitarian property-dominated distribution of power). It is arguable that with a strong central authority devoted to unfettered capitalist expansion, India could have achieved a higher rate of economic growth over the past two decades. By removing restrictions on domestic and foreign capitalists, suppressing the consumption demands of the middle and organized working classes, and abandoning even the limited redistributional efforts of the past, a strong Indian government might have been able to create conditions much more favorable to private capitalist accumulation. But at best such a framework would have promoted a very uneven and politically tenuous form of economic development. The Chinese experience suggests that a pattern of development combining economic growth with an increasingly equitable and self-reliant society requires not only a stronger central authority but also a dramatic shift of political power away from those classes who benefit from inequality and foreign involvement. Without such a fundamental transformation of political-economic conditions in India, it is difficult to be optimistic about India's prospects for attaining the several economic objectives of development.

DISCUSSION

Padma Desai, Harvard University: I have undertaken the task of commenting on the two papers by Barry Richman and Thomas Weisskopf with considerable hesitation. Coming from an Indian, my assessment of the contents and especially the conclusions of these papers is likely to be suspect. I shall try my best to avoid the temptation of being less than impartial; and I hope that any prejudice on my part will not be prejudged.

I also happen to have some reservations about comparing and contrasting the problems and performance of these two countries. There are, of course, similarities between the two in terms of their enormous land and population masses and the historical burden of long foreign exploitation. However, each has been operating under a different political system; besides, their record of economic growth is so brief as to be more an experiment defying attempts at prediction rather than a sustained experience. Moreover, the problems of each are staggering. Perhaps my familiarity with the mind-boggling Indian scenario breeds some caution. The Chinese scene is equally complex with the additional handicap of lack of reliable information on China.

With these introductory remarks, I proceed to comment on how successfully these courageous men accomplish the task of contrasting Chinese and Indian economic performance and explaining the sources of their differential achievements.

I begin with Richman's paper. He provides a conceptual framework for explaining the better economic performance of China in terms of its superior social development. The sequence of argument proceeds as follows: the higher the level of social development, the greater the willingness and ability of the people to work "hard and effectively on a national scale for goals that inspire them"; as a consequence, economic growth is more rapid.

Social development, in turn, can be identified in terms of progress not only in education, health, social mobility, and so on but also in the attitudes, values, motivation, and behavior patterns of the population. Thus Richman states: "China's party leadership has capitalized on, modified, created, and put into widespread application attitudes and values that are conducive to economic development—such as nationalism, the desire for achievement, work motivation, pride, dedication, loyalty, self-improvement, self-confidence, altruism, cooperation, resourcefulness, thriftiness, frugality, a more scientific view of the world among the masses, and so on."

Furthermore, China's leaders have sought to create such a perfect state of social development by a massive and sustained employment of communist ideology and organization.

Obviously it is impossible to test this qualitative framework rigorously. Instead, Richman picks out certain criteria of social development, such as level of education, work motivation, social mobility, income equality, employee participation, standard of health, etc., and then identifies them quantitatively for both China and India. For example, high labor productivity and low absenteeism indicate superior motivation; then again, educational and career opportunities are suitable indexes of social mobility and so on.

On the basis of tenuous observations, he concludes that on almost all counts of social development China has done better than India; therefore, by inference from his model, Chinese economic performance is superior to Indian; and he proceeds to assert that there are quite a few economic indicators which support this claim.

I have reservations both about the analytical framework and its actual application to China.

To begin with the conceptual shortcomings of the framework: a heightened level of social awareness with its attributes can lead to faster economic growth if its total contribution to the growth process is positive. Richman does not, however, provide us with the dynamics of the interaction from social development to economic growth and so I am left worrying about the negative contribution to economic growth of some of the elements associated with a state of social awareness. For example, there is a critical point at which ideological exhortation and enforced discipline in a society such as China begin to contribute negatively to growth. Also, in traditionally hierarchical societies such as China and India, a clear demarcation of authority rather than an egalitarian participation at each stage of the work process may be more conducive to productivity.

Richman's own awareness of the tradeoffs between enforced egalitarianism and productivity and between ideological extremism and economic growth comes through almost as a letdown on the concluding page of the paper when he declares: "If China does evolve into a truly advanced economy, it would seem that some of the more important aspects of pure Maoist-Marxist-Leninist ideology would have to be compromised considerably in the process."

As for the actual application of the framework to China, the Chinese record of the last twenty-five years gives evidence of the contradictions between a presumably superior societal state and a productive economy. In other words, the Chinese leaders seem to be less certain of the positive link between social development and economic growth. As a result, we have, as Richman points out in a brief section, the phenomenon of the excessive exuberance of the Great Leap Forward and the ideological excesses of the Cultural Revolution followed by some economic rationality.

I have also some reservations about the tenuous evidence in terms of which the author argues that China is a superior societal state and hence a more productive economy than India. I shall comment on that aspect in my concluding remarks.

I now go on to the second paper by Weisskopf. He argues that China has performed better than India on all the three counts of economic growth, economic equity and self-reliance in the recent period.

He attributes the differential performance in self-reliance in large measure to the differences in their basic strategies of development. It is argued that the Chinese system is more self-reliant because it has not relied to an equal degree as India on foreign private investment, foreign aid, imported technology, and so on. It is further argued that the Indian reliance on foreign private investment has led to economic dependence on foreigners. I see here a ready willingness to equate India with a South American banana republic. In this context, it is possible to argue that given India's size, resource diversity, and political sophistication, India has been quite aware that she could absorb more private foreign investment without compromising economic or political independence. After all, as we Indians like to say, one cannot walk with an elephant in one's pocket.

It is also arguable that the Indian strategy of utilizing aid and limited private investment to finance imports of technology in order to narrow the technology gap has produced far more substantial and variegated technological absorption in India than has been the case with China: thus witness the recent report of Norman Borlaug on the state of agricultural research in the two countries. Finally, Weisskopf must not forget that the Chinese tried to use Soviet aid and were *forced* to do without it only because the Soviet Union withdrew abruptly from the scene: the wisdom attributed by Weisskopf to the Chinese was really Hobson's choice.

As for the superior Chinese performance in economic equity, Weisskopf traces it to the Chinese strategy of the abolition of private property, creation of mass employment, and extensive provision of social services. It seems to me that some societies which have abolished private property have ended up by creating other types of inegalitarian privileges, such as those arising from bureaucratic abuses, whereas other societies which have retained private property also are characterized by varying degrees of economic inequality. Thus it would seem that the abolition of private property in itself does not necessarily result in greater equality.

Nor is it accurate to exaggerate the prevalence of equality in the Chinese countryside as measured by the provision of employment and other services. What the Chinese seem to have accomplished is widespread distribution of food and the most rudimentary types of shelter, education, and medicine to its population in a commune-type organizational system in which free mobility is prohibited. However, *within* this overall arrangement, there must be differences in the levels of remuneration, in the quality of social services provided from commune to commune, from village to village, from one factory to another, and from some favored regions on the Eastern seaboard to the outlying wilderness of Tibet. I refuse to believe that if one has seen one commune or factory, one has, like Spiro Agnew, seen them all.

In the concluding section, the Weisskopf paper attempts an explanation of the better economic growth performance of China. It is argued that China has grown faster as a result of its social and ideological transformation, its authoritarian political system, and its egalitarian strategies. This section of the paper resembles Richman's framework which seeks to relate economic growth to superior social and ideological development. I have already expressed my reservations about this framework earlier.

My overriding hesitation about both the papers is essentially methodological. Some of us who have been working on India for quite a few years find it baffling to provide decisive answers to issues such as how self-reliant or egalitarian or technically mature India happens to be in spite of the mass of information and extensive access to it by scholars for scientific scrutiny and evaluation—unlike in China. Similarly, the bits and pieces of information which are allowed to trickle in from China are certainly inadequate to provide answers to similar issues in the Chinese context, notwithstanding the assertions of China-watchers from Mainland America.

Jerome Cohen has recently characterized the blinkered activity of several Sinologists as "Marcopolities." I am reminded of a funny story by Stanley Karnow who stayed on to visit Peking University after the Nixon entourage had left. Out of nowhere, an apparently random sample of Chinese students appeared to entertain and inform him. Karnow was congratulating himself on his success in meeting this unbiased group until one of these students said: "As I was telling James Reston last week . . . ".

When facts are scarce and scholarly analysis and scrutiny are rare because infeasible, how does one arrive at the critical judgments that are necessary to evaluate and compare the Chinese society and economy with the Indian? And so I ask myself: How can one be so sure, as Richman, that Chinese managers are good and Indian managers are incompetent? Perhaps there are good managers and bad managers in both systems. How can one assert, as both papers do, that China is technologically more advanced than India? Where is the systematic and detailed documentation of the research activities in the industrial, agricultural, and educational institutes and farms and factories in the two countries? Is it really true that China has solved its unemployment problem? What does such a statement mean except to imply that labor in China is not free to move where it chooses to? I am still at a loss to decide if the Chinese promote productivity by rewarding merit or via ideological devotion. How does the whole system of rewards and penalties, which is the essence of productive activity in any society, really function in China?

I trust, therefore, that I will be excused if I remain on the fence, waiting for the all-too-missing evidence and careful analysis of the Chinese experiment before I accept the conclusion that it Pareto-dominates the Indian economy on all dimensions. I cannot help recalling listening in early 1967 at Columbia University to a noted Sinologist of an ideologically quite different persuasion from the authors of today's session. He was favorably comparing the Indian economy with the Chinese, using the Indian Plan-document statistics, representing mainly *ex ante* aspirations, and Chinese *ex post* performance. I have a distinct impression that we have the reverse phenomenon in the two papers today: *ex ante* Chinese (and Sinological) assertions being compared with *ex post* Indian realities.

China will have to be opened up by the Chinese to far more objective scrutiny and the suspension of disbelief will have to be renounced by the China-watchers before a realistic assessment can be expected on the issues that both the papers today claim to have settled but have only barely raised. This may well take more than a generation: a time scale which is atomistic in India's and China's civilizations but which is unhappily too long for the American. One must not also forget that much can, and historically often does, happen in two countries with such diverse and difficult problems of domestic management and international relations when one shifts to a time scale rather longer than that implicit in the papers today; and, indeed, little of such prospective performance can be captured by our analysis even if we supplemented our economic apparatus with historical and sociological analysis. I like to recall Selig Harrison's disturbing forecast of India's political balkanization and disintegration in his well-known book, *India: The Most Dangerous Decades*, and how, when the decade and more had passed, a witty friend of mine from Tamil Nadu in India approached him at a Washington party and said: "We tried hard to implement the program you had laid down for us, but you know how inefficient we are." And I have a matching story for China too. As Weisskopf certainly knows, unlike the subjects of their study, the Sinologists and the Sovietologists at Harvard sup at the same subsidized table in peaceful coexistence. As I stood one day in the line behind two Sinologist friends in animated discussion of Chinese politics, the possible fragility of our predictions regarding China's political and economic future dawned on me as I realized that one was a reactionary Sinologist if one wished Mao Tse-tung to die before Chou En-lai and a revolutionary Sinologist if one wished the opposite.

Rather than conclude on these skeptical thoughts, let me raise two questions to leave with the authors for their further reflection. First, given the totally different political systems which India and China inherited and possess, for historical reasons which neither can be really given credit or discredit for, would it not be a more meaningful question to ask whether each is efficient or equitable *within the constraints* specified by the political system? This is surely a necessary complement to the question normally posed, as in today's papers: i.e., whether one *overall system* is superior to the others on efficiency or equity grounds. Next, even if the overall Chinese system were Pareto-superior on desired dimensions, what does it really imply about the critical choices before other developing countries? And I mean here not merely the predicament of the Indian economist who favors the Chinese solution but knows that he can neither order it into existence nor advise Mrs. Gandhi to implement it. I also mean the really thorny question of how special to China is the presumed success of its revolution in accomplishing the goals that Weisskopf, for example, sets out. For example, when one compares the Chinese and the Soviet experiences, one is struck by the contrast between Soviet ruthlessness and failures in its treatment of agriculture and the Chinese reasonableness and successes—a contrast that might be attributed to personal differences between Stalin and Mao or to philosophical differences between the Slavonic temperament given to extremes and the Confucian soul tempered by wisdom. But to me, the striking difference, of course, was that while Lenin, almost by accident, seized power before the revolution was accomplished in Russian society, Mao accomplished the revolution before seizing power. One has only to read Jan Myrdal's *Chinese Village* to see that the bulk of the kulaks must have been liquidated in the course of the Long War itself. Unless and until these and other such elements pertinent to the Chinese experiment's successes and failures are carefully disentangled, one has not really made much progress in effectively contrasting China with other countries, whether India or Brazil.

JOHN G. GURLEY, Stanford University: There appeared fifteen years ago, in the *American Economic Review*, an article by Wilfred Malenbaum on "India and China: Contrasts in Development Performance." As far as I know, that was the first and last time these two countries were compared in the pages of the American Economics Association's journals. This session now extends the story that Malenbaum started.

Malenbaum showed that, for the 1950's, China's growth rate of real income per capita was two to three times higher than India's. He attributed about half of the differential to China's higher rate of domestic saving and investment and the other half to the greater productivity of this investment, which he thought was the result of the Chinese putting more investment into agriculture, getting more out of their industrial investments, and centralizing the control of these capital expenditures. He concluded that: "The present analysis . . . indicates economic developments overwhelmingly favorable to the Chinese effort, both with respect to actual performance and to potential for further growth." The author, however, declared that the lesson to be drawn was not that "totalitarian methods serve better than those conceived and implemented under democracy," but rather that the Indian government simply had to get off the dime.

An interesting fact about this article is that its appearance coincided with the beginning of a sharp and rather prolonged downturn in China's economy, thereby temporarily, at least, throwing serious doubt on Malenbaum's implied forecasts. But what is even more striking about the article, from our present vantage point, is how confidently the author assumes that "development" can be measured by income per capita and can be achieved with a higher saving rate and a more efficient allocation of saving to capital formation. That's all there was to it in those innocent days!

A decade later, Gunnar Myrdal, in his monumental work, *Asian Drama*, lambasted all such circumscribed analyses, especially when they were transplanted in Asia. Myrdal criticized this type of growth theory for its simple-minded concern with only a few economic variables to the neglect of a host of other economic, social, and political considerations, all of which were closely interrelated. Developing nations, for Myrdal, were complete social systems made up of people who were engaged not only in producing, saving, and investing, but who also had certain levels of health, education, nutrition, culture, and housing, who had definite attitudes toward life and work, who acted through a variety of institutions, and who designed and implemented policies to change certain features of the system. It was Myrdal's view that "development" could only mean an upward movement of the entire social system. The main resistance to such an upward movement he saw in the retarding attitudes of peoples, reinforced by their institutions, and cemented into place with their misery and ignorance. Thus he called for a frontal attack on all the major problems at the same time. If development policies, he wrote, are "mainly directed at economic development in the narrow sense, they will prove less than effective." However, he was well aware that it was difficult "to carry out reforms that offend against established institutions and attitudes, especially since those in power . . . often share these attitudes and have a stake in preserving the institutions" they are supposed to reform. The obvious implication was that, at least in the more desperate cases, only a full-scale revolution by the peasants against the propertied classes and their official representatives could open the way for a serious development effort—though Myrdal never said this in so many words. He shied away from completing the prescription of how peasants (and workers) could organize themselves into a revolutionary force to overcome their oppressors and their own ignorance and misery; he recoiled from armed conflict.

The papers by Thomas Weisskopf and Barry Richman both contain the broader analyses urged by Myrdal, and in this respect they mark an important advance over the older formulations. Both authors, in assessing the development performances of the two countries, are immediately occupied with a swarm of social variables. Weisskopf organizes them around the three economic goals of growth, equity, and self-reliance, while Richman relates them to his more general theme about the productivity of labor. The frameworks are similar, the choice of variables to be studied about the same, and the findings of China's superiority almost identical. Despite these likenesses, there are a few differences between the two papers.

Richman's thesis is that economic development comes largely from the willingness and ability of people to work hard and effectively for inspiring goals, which in turn is a result of social development—i.e., progress in human welfare, attitudes, and institutions. Social development is mainly a matter of good ideas, of ideology and the strength of the commitment to it. Richman, therefore, suggests that China's superiority lies basically in her superior ideology (except when the commitment to it becomes too strong), which has speeded her social development, thereby raised the productivity of her people, and so boosted her growth rate of output per capita. The causal path runs from ideology to social development to labor productivity to growth rates. It follows, for Richman, that India's performance could be much improved if the Indian government would fashion and promote an ideology more conducive to development. This, I believe, starts from the wrong end.

While ideas can be a social force, they also arise from the real everyday activities of people. They come out of these activities and in turn influence them, which is to say that people, in changing the world, at the same time change themselves. Peasants who overthrow their oppressors not only change the class structure and institutions of their society but in the revolutionary process change their own conceptions of the world, their values, needs, abilities, and aspirations. The postrevolutionary economic policies flow out of this historical interaction of material and human development. Richman would presumably consider such economic policies—e.g., cooperative farming—as the materialization of a good idea, the idea of cooperation. A more fruitful way, however, is to view these policies as growing out of a revolutionary process, which itself has deep historical roots and which gives the peasants not only control over their own lives but also an understanding of the causes of their poverty and hence of its solution. This is necessarily a complicated story, involving as it does a web of interactions between theory and practice, between actual struggles and the understanding of them. The revolutionary process has unfolded in China in complex ways, while it has been developing more slowly and in different forms in India. All of this can be explained only by hard digging into the historical and dialectical development of each country's productive forces, class structure, and superstructure of values and institutions. Richman makes short work of it: China simply had a better idea. In much the same way, Malenbaum concluded that China had simply more willpower, more get up and go.

Weisskopf's answer is more carefully worked out, but it contains some similar weaknesses. China outperformed India, he tells us, because China did this and that and India did not. But why? It appears that part of the answer is of the Richman type: the greater success of the Chinese in achieving equity was because of the particular development strategy they espoused. This sounds like "better ideas" all over again. Later, Weisskopf, in accounting for China's success in attaining self-reliance, seems to revert to something like a Malenbaum-type explanation: China's better record in this area, he says, "has resulted largely from deliberate strategic choices of Chinese leadership." They simply decided to do it, while India, in principle, could have done the same thing but chose not to. Regarding growth, China's superior performance was owing to her particular approach to development—for example, to her decision to bring about a radical transformation of social and economic institutions.

These "explanations" are a bit superficial, for they suggest that "India" and "China" each sat down, like Rodin's thinker, to work out the best thing to do. China, with more brains, a firmer resolve, and wider options, won out. Weisskopf, however, unlike Richman, gets to the heart of the matter when, in his conclusion, he ascribes China's wider options to the fact that the Chinese leadership achieved "a truly revolutionary redistribution of power" and acquired "the authority and the capacity" to choose and implement its policies effectively on behalf of the peasants and workers—whereas India did not. Now that's really saying something, but it should be only the beginning, not ending, of an analysis.

Marx said that men make their own history but not exactly as they please. Richman especially, but to a lesser extent Weisskopf too, exaggerates the degree to which people freely make decisions. It would also be one-sided to say that the Indians and the Chinese did what they were compelled by history to do. But that viewpoint would be a healthy corrective to the maladies of both papers, for it would suggest that China's economic superiority over India in the past few decades is perhaps fleeting, a reflection not of more brains, more resolve, better programs, or more brilliant strategic choices, but of the two countries being in different stages of historical development. For centuries, China was a door mat for preying capitalist nations, and her record was, for long, dismal compared to Japan's. But these differences are now rapidly disappearing. India was once economically superior to Britain, then became an exploited colony. In the meantime, Britain, as the kingpin, has come and gone, and India is slowly reemerging, gathering strength, augmenting the revolutionary forces against the old powers. Uneven development has been the rule for centuries as nations have moved into and through the capitalist to the socialist mode of production. One has to have some conception of where the world is going to be able to speak wisely about present, but perhaps transitory, superiorities.

EAST-WEST TECHNOLOGICAL TRANSFER ISSUES AND PROBLEMS

International Technology Transfer: Forms, Resource Requirements, and Policies

By EDWIN MANSFIELD*

Recent years have seen a greatly increased interest in the international diffusion of new technology. For a variety of reasons, including developments in the theory of international trade and the emergence of various policy issues related to the transfer of technology, economists have been led to inquire more seriously into the process of international technology transfer. Because of the complexity of this process, and the fact that it has received relatively little attention in the past, our knowledge of it is still rather meager, particularly when compared with the demand for information by policymakers facing questions related to this process. In this paper, my assignment is to describe briefly various forms of technology transfer, to discuss the problems and costs involved in the transfer process, and to comment on some aspects of *U.S.-USSR* technology transfer.

I. Technology Transfer: Forms and Problems

In the literature concerning technology transfer, there is frequently a tendency to slur over some important distinctions, with the result that unnecessary confusion sometimes occurs. First, it is important to distinguish between *vertical* technology transfer and *horizontal* technology transfer. Vertical technology transfer occurs when information is transmitted from basic research to applied research, from applied research to development, and from development to production. Needless to say, such transfers occur in both directions, and the form of the information changes as it moves along this dimension. Horizontal technology transfer occurs when technology used in one place, organization, or context is transferred and used in another place, organization, or context. The problems involved in transferring technology from one country to another are quite different when the transfer is vertical as well as horizontal. In general, the difficulties and costs are much greater under these circumstances than if only a horizontal transfer is involved.

Second, it is important to distinguish between various types of technology. For example, as George Hall and Robert Johnson point out, it frequently is useful to differentiate between *general* technology (information common to an industry or trade), *system-specific* technology (information concerning the manufacture of a certain item or product that any manufacturer of the item or product would obtain), and *firm-specific* technology (information that is specific to a particular firm's experience and activities, but that cannot be attributed to any specific item the firm produces). Also, it is important to distinguish between several phases of the process of technology transfer. The first phase frequently is the export of a new material or product by one country to another. This phase, which Vernon Ruttan and Yujivo Hayami call *material* transfer, is often followed by *design* transfer, which is the transfer of designs, blueprints, and the ability to manufacture the new material or product in the recipient country. Finally, there is the phase of *capacity* transfer, which occurs when the capacity to adapt the new item to local conditions is transferred. Clearly, the last phase—the phase of learning how to learn as well as to use what others have learned—is quite different from the earlier phases and much more difficult and costly to achieve. It is a phase that many countries have yet to enter in the more sophisticated areas of technology.

---

* Professor of economics, University of Pennsylvania. The findings described in this paper resulted from work supported by a grant from the National Science Foundation. Also, some of them are related to the work I carried out while I was a Fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford. Thanks go to Rolf Piekarz for providing relevant documents, materials, and advice concerning the material in section III.

Having touched on the differences between various types of transfers, various types of technologies, and various phases of the transfer process, I want to turn to the kinds of problems involved in the transfer of technology. Economists sometimes assume that technology is like a sheaf of blueprints and that all one has to do is ship off the right set of papers. Unfortunately, it isn't that simple or costless. For one thing, the available evidence, both recent and for earlier periods, indicates that publications and reports are a much less effective way of transferring technology than the movement of people. To transfer "know-how," much of which is not written down in any event, there is frequently no substitute for person-to-person training and assistance, some of which may have to go on for extensive periods of time.

Also, the technology that is transferred must often be adapted, if it is to meet the needs of the recipient. Because markets in the recipient country are smaller, because input prices are different, because the vendor infrastructure is different with regard to capability, cost, and quality, because of national differences in taste, climate, and so forth, the technology must be adapted. This process of adaptation can be more difficult than it may seem. Just as in the original innovation, it is very important that a proper mating occurs between the technological considerations, on the one hand, and the more purely economic considerations, on the other. (See E. Mansfield and S. Wagner.) It is easy to cite cases where, because of errors in either the private or public sectors (or both), this mating resulted in a deformed offspring.

II. Technology Transfer: Resource Costs

As emphasized in the previous section, the transfer of technology is by no means costless. Like any economic activity, it uses up resources. How great are the resource costs involved in a particular technology transfer, and what are the important factors determining these costs? As Kenneth Arrow and others have pointed out, this is an important question, and one that has received very little attention. To make any headway toward answering this question, it is necessary, of course, to construct some operational measure of the resource costs of technology transfer. When a plant is built abroad based on *U.S.* technology, there generally are outlays for engineering consultation prior to building the plant, costs of transferring engineering information concerning the process and/or product and of supervising the detailed engineering, research and development (*R&D*) costs involved in adapting the technology, and costs due to low labor productivity and poor product quality during the period when the workers are learning to utilize the new technology. David Teece, in his doctoral work (carried out under my supervision), uses the sum of these items as a measure of an important segment of the costs of technology transfer. It represents, at least crudely, the value of the resources used up in transferring to engineers and workers the relevant technology, other than that embodied in purchased equipment and materials. There may, of course, be an appreciable amount of technology transferred through the purchase of equipment and materials, but the focus here is on the costs of transferring "naked" or "unembodied" technology. Royalties are excluded (here, but not in other parts of the relevant study) because they are not a payment for resources used to transfer the technology, but a payment for the right to use it.

To estimate the magnitude of the costs cited above, data were obtained by Teece concerning twenty-six projects in which a multinational firm transferred technology abroad. In each case, a new plant utilizing the technology was built by the transferee. In the language of the previous section, most of these transfers were horizontal (not vertical as well), and practically all were system-specific and in the design phase. Table 1 shows the average and range of the relevant costs for the projects, each cost being estimated by the firm involved.[1] It also shows the mean and range of the ratio of this cost to the total cost of establishing the new plant abroad. The results indicate that these costs of transferring technology are a substantial portion of the cost of establishing a new plant abroad, particularly for the electrical and machinery firms. On the average, these technology transfer costs equaled about 36 percent of the total cost for the electrical and machinery projects, and about 10 percent of the total cost for the chemical and petroleum refining projects. (Because the technology in chemicals and petroleum refining is so different from that in machinery and electrical equipment, the sample is split into two parts, here and below.)

TABLE 1—RESOURCE COSTS OF TRANSFER OF TECHNOLOGY, 26 CASE STUDIES[a]

	Machinery and Electrical Equipment	Chemicals and Petroleum Refining
Mean Cost ($ thousands)	1,197	1,224
Range of Costs ($ thousands)	34–5,850	50–7,425
Mean Percent of Total Project Cost[b]	36	10
Range of Percentages of Total Project Cost[b]	11–59	2–22

[a] Technology transferred through the purchase of equipment or materials is excluded here. For the items included in the cost of technology transfer, see section II of the text.

[b] Total project cost equals the cost of establishing the plant, including transferring the relevant technology, obtaining equipment, and building the plant. However, for reasons given in section II, royalties are omitted.

Several hypotheses seem important in explaining the large differences among projects in the ratio of these technology transfer costs to the total cost of establishing the plant abroad. First, one would expect that this ratio would be higher if the technology that is transferred is relatively new than if it is older technology. Since newer technology tends to be less well understood (by the transferrer as well as the transferee), these costs tend to be higher. Second, one would expect, holding the age of the technology constant, that this ratio would be higher if the transferrer had built no previous plants that used this technology. The problems and costs involved in transferring an untried technology tend to be much greater than if the transferrer has been involved in many previous applications of the technology. (The former types of cases typically involve both horizontal and vertical transfers, in the language of the previous section.) Third, one might expect this ratio to be higher if relatively few firms in the world had applied the technology at the time of transfer. This variable supplements the previous one because, whereas the latter is an index of the transferrer's experience with the technology, this variable is an index of how much worldwide experience there has been with it and of how widely this experience has been diffused. (However, an identification problem may exist here because more firms may have applied the technology if this ratio is low.) Fourth, one would expect this ratio to be higher if the organization to which the technology is being transferred has had relatively little experience in manufacturing items of the general type produced by the plant. Clearly, the problems and costs involved in transferring technology tend to be greater if the transferee is relatively inexperienced.

---

[1] It is important to note two points about Table 1. (1) Some costs associated with learning by workers may be closely related to the costs of equipment and to new operating conditions. Also, the costs in Table 1 exclude costs incurred before the decision was made to build the plant. For these and other reasons, the figures in Table 1 are only crude approximations. (2) Most of these costs would have been incurred if the technology had been transferred within the United States, rather than to another country. Indeed, in some cases these costs would have been higher (according to executives and engineers) if the technology had been transferred within the United States, because of higher wage rates here. Thus, the figures in Table 1 represent the indicated costs of transferring the technology, not the extra cost of transferring it across national boundaries.

To test these hypotheses, it was assumed that

$$C_i = \alpha_o + \alpha_1 S_i + \alpha_2 A_i + \alpha_3 E_i + \alpha_4 F_i + Z_i, \tag{1}$$

where C_i is the technology transfer cost (expressed as a percentage of the total cost of establishing the plant abroad) for the ith project, S_i is a dummy variable that is 1 if there have been no previous applications of the technology by the transferring firm, 0 otherwise; A_i is the number of years that the relevant technology has been in existence when the transfer occurred; E_i is the number of years of manufacturing experience in the relevant area of the transferee at the time of the transfer; F_i is the number of firms that had applied the technology at the time of transfer; and Z_i is a random error term. Least-squares estimates of the α's were obtained, and the results seem in general to support the hypotheses listed above. Since the study on which they are based is not yet completed, these results are highly tentative. But they seem of interest since, to my knowledge, this is one of the first systematic studies of the factors associated with the resource costs of technology transfer.

III. U.S.-USSR Technology Transfer

Finally, I shall say a few words about *U.S.-USSR* technology transfer, a topic that has received considerable attention in recent years. As is well known, the Soviet Union devotes very substantial amounts of money to research and development, and has achieved notable successes in many technological areas. Nonetheless, Soviet technology lags behind that of the United States in many important areas, including computers, integrated circuits, and telecommunications. Of course, one important reason why its civilian technology lags behind is that the Soviet Union has put such high priority on military and space projects. Also, the Soviets have encountered important difficulties in getting new technology out of the laboratory and into widespread application. These difficulties seem to have been due, in part at least, to the sharp separation of *R&D* from production, which has tended to reduce the economic relevance of the *R&D* carried out and to thwart the vertical transfer of technology. Also, the incentive system facing Soviet managers seems to have discouraged innovation of many kinds, as well as the horizontal transfer of many kinds of technology.

In the past few years, there has been a marked increase in the amount of technology transfer between the United States and the Soviet Union. Although there has been widespread support for the recent spirit of detente, many observers have warned that the United States should be cautious in this area. Mindful perhaps of the Russian wheat deal, many economists have been worried about what we are getting in return for relaxation of controls. This concern has, of course, been accentuated by the asymmetry of the bargaining relationship, the State Committee on Science and Technology being in a somewhat monopsonistic position vis-à-vis American firms. Many American firms are worried about patent rights, and some have pressed for retroactive patent recognition. Further, they are worried that the Soviet market may turn out to be much smaller than some people have estimated, and they are concerned about Soviet entrance and pricing in some markets.

All in all, both the benefits and the costs to the United States of increases in technology transfer seem remarkably hazy. For example, in the view of many experts, the effects of relaxing controls on items like certain large computer systems would have only a modest effect on Soviet military capabilities (see C. Wolf). Yet others seem much more concerned about the relaxation of such controls. On the economic front, there is also a wide diversity of views, as evidenced by recent Congressional hearings on the subject. And the political or diplomatic benefits of increased technology transfer, which may be their most important rationale, are hard to predict. As Wolf remarks, "Each of us remains his own expert on the matter of political gains" (p. 7).

Turning to the much narrower topic of the transfer of economic knowledge, it is worth noting that *U.S.-USSR* technology transfer extends in a significant way to the economic aspects of science and technology, as well as to the purely technical aspects. The *U.S.-USSR* Joint Commission on Science and Technology established a *U.S.-USSR* Project Group on the economics of scientific and technological information, of which I am the *U.S.* chairman. William Baumol, Sanford Berg, Zvi Griliches, Lester Lave, Robert Willig, and I will go to Moscow this summer for the first joint symposium with the Soviets, the topic being the application of benefit-cost techniques to scientific and technological information. We hope that the proceedings will promote a better understanding in both countries of this difficult and important topic.

The Economics of East European Technology Imports from the West

By EDWARD A. HEWETT*

Governmentally imposed constraints on technology exports by Western firms to Eastern Europe[1] are no longer an important consideration outside the limited area of military hardware and related technology. Likewise, discriminatory import barriers directed particularly at East European products are also disappearing. As these political constraints lose their power, the level and composition of East-West trade will increasingly reflect more complex economic and systemic factors, which means that these trade flows are for the first time really becoming susceptible to economic analysis.

This paper is an attempt at such an analysis for East European technology imports from the West. While these are only one aspect of East-West economic relations, they are an important one both because they are closely linked to other aspects, such as East European export performance, and because they provide a particularly illuminating example of the effect of East European economic systems on the level and composition of imports from the West.

I.

"Technology" is considered here to include both specific knowledge about physical production, embodied for example in machines, designs, formulas, etc., and also more general "know-how" including, for example, organizational procedures concerning coordination in production, procurement, marketing, and research and development (*R&D*).

Eastern Europe has sought to purchase Western technology, primarily physical production technology, as part of its attempt to achieve high growth rates through continuous improvements in factor efficiency. For the small East European countries, imports are an important source of growth, technological imports an important source of technological change, and product exports the major source for financing both. Understandably, then, for most of the Western technology that East European countries buy, they seek to ensure that, in addition to increasing factor efficiency, the purchase improves the balance of payments with the West.

Through the mid–1960's the majority of East European technology imports were through direct purchase of licenses, machinery and equipment, and complete plants. However, in recent years, and particularly in the small East European countries, more complex institutional arrangements have come about which are typically grouped under the general rubric of Industrial Cooperation Agreements (*ICAs*). These are agreements between

* Assistant professor of economics, University of Texas at Austin. The research for this paper was conducted while I was a Visiting Scholar at the Világgazdasági Kutatóintézet in Budapest during September–December 1974. I am particularly grateful to my colleagues at the Institute, as well as to other Hungarian economists and government officials, who contributed immensely to much of the information and some of the ideas presented in this paper.

[1] "Eastern Europe" is taken here to mean Bulgaria, Czechoslovakia, East Germany, Hungary, Poland, Rumania, and the Soviet Union.

Eastern and Western firms in which usually the Western partner provides the technology embodied in machines, equipment, and licenses, and the Eastern partner repays later with products resulting from the new processes. The specific forms of the *ICAs* vary. (United Nations, 1973, provides a general review.) They can involve, for example, simple purchases of complete plants or licenses in exchange for later payment with the resulting products; subcontracting, in which the Western partner provides technology and possibly some inputs for producing a certain component and the Eastern partner repays in a fixed amount of components; coproduction and comarketing, where the partners specialize in parts of a single production process, assemble the final product in one or both countries, then divide up marketing areas; and finally, joint operations on third markets. One other form of *ICA*, the joint venture, is only possible in Hungary, Rumania, and Yugoslavia, and only in Yugoslavia (which is not being considered in this paper) has it assumed any real significance. Joint venture agreements allow for up to 49 percent ownership, but there are substantial differences among the three countries in most of the major provisions for the agreements. (C. McMillan and D. St. Charles provide a good comparison.)

While some *ICAs* do involve technology transfer from the East to the West, the flow is predominately in the other direction. East European economists argue that the *ICA* is the most efficient form for importing Western technology from several points of view (K. Szénásiné-Zboróvári, M. Simai). First, the *ICA* seems to increase the probability that the East European country can obtain the most modern technology for sale in the West and that it will be assured of adequate help from the Western partner in absorbing the technology, since the Western firm must accept and use, or market, the resulting products. Second, the Western firm will force the Eastern enterprise to meet higher quality requirements and guarantee smoother operation of the production line than are typical in most socialist enterprises. Third, *ICAs* are expected to improve access to Western markets, both because Eastern enterprises can learn from the Western firm's marketing organization and because they can avoid some of the high costs attached to independent entry into Western markets. Finally, the so-called "complex-barter" aspects of *ICAs* mean that little money is involved and that there is a more or less guaranteed balance of payments effect arising from a fixed export commitment signed when the technology is imported (United Nations 1970).

Even accepting these propositions as being substantially correct, they only address one side of the question, that of the most efficient form for extracting from Western firms the technology which Eastern Europe wants to acquire. The other side is whether Eastern Europe, given its goals and constraints, is buying the correct amount, quality, and quantity of Western technology, and if it is using it as efficiently as possible.

Very little useful information is known about the actual performance of *ICAs* in that regard, in part because they have only recently begun to grow beyond the insignificant level of the early 1960's. A more fundamental impediment to learning more about *ICAs* is that most of the requisite information resides in Western and Eastern enterprises which will not allow the detailed access to their records and organizations necessary for serious research.

In an attempt to gather the information which does exist and to derive hypotheses useful in more detailed research, I have undertaken a study of the Hungarian experience with *ICAs*. Hungary now accounts for about one-half of all *ICAs* existing between Eastern Europe and the West (interview material); thus it provides an excellent case study of East European problems with *ICAs*. Although it might appear that Hungary is a special case because of the 1968 Economic Reform, in fact that Reform provides crucial new information about enterprise attitudes toward technology transfer in Eastern Europe. It must be emphasized that the conclusions which follow are very tentative; and firmer conclusions will not be possible until, and if, more data are published and detailed case studies are completed.

II.

Only a general outline of the post-1968 Hungarian economic system is necessary here (for details see B. Balassa, D. Granick, and M. Tardos). Hungarian enterprises receive no obligatory plans from the government; they alone are legally responsible for plans and contracts covering current outputs and inputs, investments, and foreign trade. The government still constructs short-, medium-, and long-term plans; however, they are much less detailed than in the old system, containing projections for aggregate and sectoral variables and considerable detail on the economic and administrative instruments which will be used to influence enterprise decisions.

Many enterprises have monopolies for the products they produce; no important products are produced or sold in anything approaching a competitive atmosphere. High tariffs, a strict import-licensing system, a foreign exchange monopoly, and export subsidies combine to protect enterprises from competition. There are strong price controls for many products, particularly consumer goods. Ministries retain substantially more influence over the enterprises than the market, primarily as a legacy of their absolute power in the old system, but also through their legal rights to appoint and dismiss managers, to control investment which goes through the state budget, and through numerous "favors" they can do for enterprises. (See Z. Hegedüs and Tardos for an interesting case study of ministry-enterprise relations.)

Consistent with the Reform, practically all proposals for *ICAs* originate with enterprises rather than the Hungarian government; in fact, the majority of those actually originate with Western firms' proposals to their Hungarian counterparts. Government policies serve to encourage *ICAs* through preferential credits for investments which will increase net exports and through tariff concessions on imports coming through *ICAs*. The Hungarian National Bank and the Foreign Trade Bank administer the credits, while the Interministerial Cooperation Committee (Tarcaközi Kooperációs Bizottság) decides on the preferences. This Committee has a strong veto power over proposed *ICAs*, which it apparently exercises mainly to prevent *ICAs* in industries where the government has decided that imports will be the sole source of domestic supplies (or at least increases in domestic supplies).

Almost all of the more than 300 *ICAs* in force now in Hungary are rather small subcontracting or coproduction arrangements. The Eastern partner is usually producing the least capital-intensive parts of the products (or the least capital-intensive finished products) using substantial amounts of imported Western materials and possibly some imported capital, but mostly its own excess capacity; then, either all or most of the product goes back to the Western partner as an input or to be marketed. For the Western partner, these "small deals" are quite profitable, since they shift the more labor-intensive, less profitable processes to an area where semiskilled and skilled labor is relatively cheap and a good deal more dependable (no strikes). There are other motivations for Western enterprises, such as avoiding high tariff and nontariff barriers to direct imports from the West. But the main concern here is what the motivation is on the Eastern side.

That is difficult to ascertain and is currently the subject of debate in Hungary. First of all, it is interesting, and quite disturbing to the Hungarian government, that large Hungarian enterprises are the *least* interested in *ICAs* of any kind; practically all of the *ICAs* involve small and medium-size Hungarian enterprises. Even for those latter enterprises the motivation to enter into *ICAs* is probably not to buy new technology or to transform the technological level of their enterprise; the agreements themselves reveal contrary preferences. In fact many *ICAs* are probably traditional trade under the name of "cooperation," through which firms can acquire otherwise unobtainable loans, investment equipment, and financial advantages (K. Zboróvári, p. 439). In sum, there is now a contradiction between the Hungarian government's ambitious aspirations and Hungarian enterprises' much more modest goals concerning technology transfer.

The source of this contradiction would seem to be closely linked with the fate of the 1968 Reforms. One of the disappointments of those Reforms is that, despite a clearly specified goal to increase competition in the Hungarian economy, very little actual progress has been made in that direction. As stated earlier, most enterprises enjoy monopolies in the products they produce. Their primary constituent, particularly if they are large enterprises, is the ministry rather than the market. The enterprises' organizational structure remains as highly centralized as it was before the 1968 Reforms, a frozen memory of the previous economywide hierarchy (M. Timár). Their activity is almost totally devoted to production, to the exclusion of marketing or research and development.

These enterprises are quite truncated by Western standards, which explains their difficulty in competing on Western markets. The most successful among Western enterprises are characterized by quite sophisticated organizational structures which execute and coordinate marketing, research and development, and production. (P. Lawrence and J. Lorsch). This explains why, in the *ICAs*, the Hungarian enterprise typically is involved only in production while the Western enterprise is involved in research and development and marketing, as well as production. The Hungarian enterprise usually appears to be most efficient in production and relatively much less efficient in *R&D* and marketing. By following the dictates of static comparative advantage, the *ICA* serves to perpetuate some of the major weaknesses of the Eastern enterprise, rather than eliminating them.

The organizational changes which would make Hungarian enterprises independently competitive on Western markets would be quite difficult and costly, requiring a substantial redistribution of power in the enterprises from directors to lower functional units, the formation of new units, promotion of younger people, etc. It seems highly unlikely that Hungarian enterprise directors will voluntarily introduce such extensive changes, even given a great deal of pressure on the part of the government. Much stronger forces than government directives will be necessary.

Probably the only truly effective mechanism for compelling these changes is increased competition in Hungarian markets, primarily through lowered barriers to foreign trade, and a substantial curtailment of the extreme power of ministries over enterprises. While there are proposals to that effect (e.g., Tardos), it seems unlikely that such drastic changes will occur soon. In the first place, it would be very expensive to introduce competition rapidly and extensively into the Hungarian economy since it would involve scrapping a significant portion of the capital stock, many bankruptcies, and a substantial redistribution of the labor force. Politically, that would be difficult to handle, and from a financial point of view would require an extremely large net capital inflow into Hungary. Also, the enterprises, the ministries, and the labor unions in Hungary comprise a formidable protectionist lobby which effectively opposes proposals for substantially opening the economy to foreign competition.

This means that the contradiction between the Hungarian government and Hungarian enterprises is likely to remain in the near future; *ICAs* will probably not soon serve as a vehicle for substantial technological transformation of Hungarian industry. Hungarian enterprises are not really interested in being "transformed"; their market situations are far too comfortable for that. On the other hand, the government will surely continue its pressure for the real technical and organizational transformation so necessary to improved factor efficiency and export performance on Western markets, as a natural continuation of its first attempt at comprehensive reform in 1968.

III.

Thorough studies of the Hungarian experience with *ICAs* are necessary to confirm the rather preliminary hypotheses presented here. Similar studies for other socialist countries are also necessary to see to what extent the Hungarian experience is unique. Most of what has been said here probably applies to other East European countries, including the Soviet Union. The overcentralization of enterprise organizations seems a common characteristic of all East European countries, and so must be the impediments that overcentralization creates for the importation and use of Western technology.

Previous to the introduction of the Hungarian Reform, the tendency was to blame problems in industrial cooperation, and East-West trade in general, on the fact that enterprise initiative was stifled by overcentralized control of their activities. And indeed there is substantial truth in that proposition. Between 1963 and 1967 Hungarian enterprises concluded about thirty *ICAs*; then in the following three and one-half years, when enterprises and not the government were the source of the proposals, 137 agreements were concluded (Zboróvári, p. 15). Probably about another 150 more have been concluded through mid-1974 (interview material). Still, it is obvious that enterprises in Hungary exhibit a quite conservative form of initiative and that centralization within the enterprise is yet another tenacious barrier to realizing the full potential for *ICAs* and thus for technology transfer.

Problems of Technology Absorption in Chinese Industry

By Thomas G. Rawski*

The ability to respond promptly and effectively to demand changes is one important distinction between advanced and backward economies. Except for small trading nations, such flexibility presupposes a highly developed capital goods sector which can meet current investment requirements. What factors affect the capacity of capital goods producers in developing countries to emulate their more advanced counterparts by transforming domestic production possibilities in response to shifting economic patterns?

The experience of China, a nation which has achieved important gains in expanding the flexibility as well as the size of domestic capital goods output, offers a useful framework for investigating this question. China's capital goods industry is presently dominated by two quite distinct groups of firms: recipients of major investment outlays and Soviet equipment shipments during the 1950's, including some with pre-1949 histories of Japanese ownership or management; and older, smaller enterprises which constitute the legacy of prewar industrial advance in the private sector and have typically received only minor infusions of imported equipment and technical aid since 1949.

The contrasting performance of these groups during the 1960's, a decade in which economic difficulties and international isolation forced domestic producers into ambitious attempts to improve quality, variety, and manufacturing techniques, provides a test of the relative importance of modern equipment and of industrial experience in determining innovative capacity in capital goods production.

With industry performance now judged primarily by the contribution of current output to immediate economic needs rather than, as in the 1950's, by its sheer volume, the second group of firms has established a clear position of technological leadership, most notably in the machinery sector.

The success of older units in substituting experience for investment points us toward models which emphasize the accumulation of skills as well as fixed assets in enlarging society's production possibilities, an approach emphasized by historians of American and Japanese development. The contributions of long-established enterprises illustrate the importance of prewar advances even in sectors which have recorded the largest increases in output and capital stock since 1949. And the inability of newer, Soviet-aided units to match the innovative performance of less well equipped plants suggests that, particularly in the presence of uncertainty, the benefits of international and domestic division of labor and specialization in capital goods production must be weighed against the less obvious gains which arise from widespread participation in the task of designing, manufacturing, and repairing new types of equipment.

* Assistant professor, Department of Political Economy, University of Toronto. E. S. Rawski commented on an earlier draft. Notes and references are available from the author.

I.

Suppose that a task T requires skill levels S_{1T}, S_{2T}, . . . , S_{nT} in each of n areas. A simple extension of the concept of "learning by doing" is the hypothesis that repeating T not only lowers its cost, but also raises potential in the various skill areas to new levels P_1, P_2, . . . , P_n which exceed the initial minima required to complete T. The resulting opportunity to develop previously unattainable skill combinations will encourage entrepreneurs to attempt more difficult tasks T^* if they believe that $P_i \geq S_{iT^*}$ for $i=1, 2, \ldots, n$ and that the gains from innovation outweigh the cost of experimentation and the risk of failure.

Although industry's skill frontier is influenced by the amount and quality of equipment, materials, education, and management, China's recent experience shows that during at least some phases of industrialization production experience may be a key determinant of the level and fungibility of industrial skills.

The significance of skill accumulation can be seen from the development of engineering both before and after World War II. China's prewar engineering industry emerged from a cycle of backward linkage and import substitution associated with new modes of production and transport imported from Europe. The appearance of steamships and railways and the subsequent growth of consumer manufactures created demands for repair services and spare parts which were initially supplied by foreigners. As Chinese experience and capital grew, native mechanics replaced foreigners, and import substitution then spread into commodities, with Chinese firms acquiring significant market shares first for parts and later for a wide range of equipment as well.

This pattern of evolutionary growth is illustrated by Shanghai's Talung Machinery Works, which began in 1902 as a ship repair specialist and, taking full advantage of the absence of scale economies and the transferability of basic engineering operations, moved successively into textile machine repairs, parts manufacture, and, finally, production of complete sets of cotton-spinning equipment.

The skills acquired by veterans of Talung and other private firms and by men who studied abroad or worked in railway shops or foreign-owned factories supported rapid growth and diversification during the final prewar decade (1927–37). In Shanghai the number of metal-processing and machinery producers using mechanical power and employing over 30 persons rose from 82 to 173 during the depression years 1931–33 alone, and output, capital, and employment for all firms in these sectors rose by about 300, 100, and 60 percent. Similar growth occurred on a smaller scale in Tientsin, Wusih, Chinan, and other cities.

The ease with which firms manned by experienced Chinese could make the transition from repair work to manufacture is reflected in the success of domestic firms in penetrating a growing range of machinery markets, particularly at the lower end of the price-quality spectrum. One survey lists 99 manufacturers of textile machines: spindles, looms, stocking frames, bowing machines, equipment for reeling and weaving silk, cotton gins and dyeing equipment. Manufacturers of milled rice, flour, cooking oil, canned goods, books, ink, leather, matches, cigarettes, candles, and soap also purchased domestic equipment.

Private engineering firms also supplied investment goods to the producer sector. In addition to producing equipment for self-expansion, machine shops sold machine tools to customers in China and in Japanese-controlled Manchuria and turned out a variety of equipment for chemical plants, cement works, smelters, mines, and railways.

By the 1930's, the engineering sector, although still small, could already help enlarge the modern sector. During World War II, domestic producers reequipped battle-damaged factories and manufactured munitions in both occupied and free China.

Despite these gains, the economic plans implemented by the new Communist government during its first decade (1949–60) made scant provision for modernizing and enlarging the inherited private engineering sector. Instead, the first Five-Year Plan (1953–57) assigned nearly half of overall industrial investment to 145 Soviet–aided projects. With few exceptions, these projects either created new facilities, such as the engineering complex at Loyang, or expanded Japanese-built plants, such as Anshan's steelworks, in which earlier Chinese participation had been limited to supplying semiskilled labor.

Shanghai, the center of China's inherited industry, turned out 22 percent of machinery output and 19 percent of national industrial output in 1957, but received only three of the Soviet-aided projects and a mere 2.5 percent of overall investment outlays during 1953–57.[1] Tientsin fared no better, gaining only a 7 percent increase in its machine tool stock during 1953–57, years in which gross fixed investment in industry amounted to over double the 1952 capital stock.

Security considerations and a desire to reduce the influence of the urban bourgeoisie may have justified this policy during the early 1950's, but the failure of Shanghai's investment share to rise above 4.5 percent of the national total even after the Korean truce, the 1956 socialization campaign, and widespread advocacy of coastal industrial expansion shows that planners expected little of China's older and smaller industrial units.

China's Second Five-Year Plan (1958–62), compiled with the expectation of continued large-scale acquisition of Soviet blueprints, equipment, and technology, was disrupted by the Great Leap Forward (1958–60) and shattered by the sudden withdrawal of Soviet technicians in 1960 and an agricultural depression caused by successive harvest failures in 1959–61.

The ensuing crisis led to major unanticipated demand shifts. Peking's belated decision to divert more resources to the farm sector increased requirements for fertilizer, insecticide, tractors, pumps, and other agricultural producer goods. Growing Sino-Soviet animosity disrupted Soviet supplies of petroleum, military goods, and equipment needed to complete unfinished construction projects.

With exports falling, grain imports rising, and the industrial powers unwilling to provide needed capital goods, the task of altering domestic production functions to meet the new situation fell squarely upon China's machinery producers.

The considerable success with which engineering firms met the challenges of the 1960's is largely attributable to the achievements of enterprises and regions which had gained little from the investment boom of the 1950's. The petroleum sector, which has achieved a tenfold output increase since 1960, is equipped primarily by converted engineering plants including former textile machine repair works. Descriptions of the petroleum machinery industry make specific reference only to smaller and older plants: Shanghai's complex, including the Talung Machinery Works mentioned above, and the venerable Lanchou General Máchine Works, a provincially managed descendant of a nineteenth century arsenal.

---

[1] Data on Shanghai investment shares are taken from an unpublished study by Nicholas R. Lardy of the University of Michigan.

The role of older firms is even clearer in the case of chemical fertilizer, a sector in which output rose from a possibly exaggerated Great Leap peak of 2.5 million tons to 9 million tons in 1965 and 20 million tons in 1972, again without major equipment imports. Domestic fertilizer equipment first appeared in quantity during 1962; Shanghai led the way, supplying 25,000 tons of equipment to one major plant. While expanding the volume of output, Shanghai firms also expanded their product line, turning out China's first equipment for urea manufacture in 1965. Small fertilizer plants, which have supplied over 80 percent of incremental output since 1965, obtain equipment from many sources, but the core of the equipment industry remains in Shanghai, where a group of over 400 factories supplied 300 sets of equipment for synthetic ammonia plants between 1970 and 1972.

Older units take the lead in introducing such new techniques as "electronic spark processing, forge pressing, vacuum casting, iso-ion cutting, argon-arc welding, electroslag welding, hot riveting, chemical and unlined hearths" into Chinese industry. Talung Machinery Works, which has pioneered in manufacturing petroleum equipment, compressors, and machinery for producing artificial diamonds, illustrates the continuing innovative success of older engineering firms.

Why are older and smaller firms better suited to developing new products and techniques than larger units? Capital cannot provide an explanation, for we know that investment planning bypassed the inherited engineering sector until 1960 at the earliest. In Shanghai's case, municipal reports indicate low or declining levels of capital formation until 1965.

The advantage of small units may arise from diseconomies of scale. Chinese observers report that smaller firms are "more compact and . . . more flexible in adjusting their production." But at Shenyang's #1 Machine Tool Works, a Soviet-built enterprise employing over 5,000 workers, organization is "swollen and ineffectual; technical control . . . highly complicated . . . the potentialities of the equipment and personnel cannot be fully developed and utilized and production technology is not likely to advance and improve."

The great strength of Shanghai and Tientsin lies in experience. With their "skilled veteran workers and experienced technical persons" and superior development of interenterprise cooperation, another legacy of the past, "old industrial bases and old enterprises . . . find it easier to tackle . . . complicated technical problems than new enterprises and new industrial bases."

With these advantages, it is the established centers which are best able to copy and modify foreign equipment samples, to extract useful information from foreign technological publications, and to apply it to current domestic problem areas. More generally, experienced firms act as technological intermediaries between the mass of Chinese producers, whose mission is to attain "advanced national levels" of quality, cost, and technique, and the outside world, whose standards become the target of Shanghai's technological aspirations.

Technical advance penetrates the economy along well-developed lines of communication which include worker exchanges among units of differing technical levels, national and local meetings focused on particular problems or on "exchanging advanced experiences," national journals for machinery, chemicals, metallurgy, and other industries, and several Shanghai journals devoted to publicizing technological gains of Chinese and foreign origin.

Campaigns to "emulate the advanced" and to "learn from Shanghai" illustrate this diffusion process. As one headline put it, "The Nation Looks to Shanghai for Production Experiences." Thousands of workers and managers, including groups from Peking, Wuhan, and other large industrial centers, visit Shanghai to "learn new techniques and to exchange knowledge" and to see that since "conditions at . . . Shanghai . . . were not any better" than elsewhere, massive investment is not a prerequisite for technical advance.

Manufacturers of steel, machine tools, diesels, pumps, pneumatic tools, sewing machines, and many other commodities judge their products by comparing them with Shanghai's, and to a lesser extent with Tientsin's. Even in cable manufacture, a field dominated by the Soviet-aided Shenyang Cable Works, "research units were established in Shanghai as centers of research and design and the experimental base for the technology of the cable industry."

During the past decade, an isolated China has taken significant steps toward overcoming economic difficulties of a magnitude which other large developing nations have rarely faced without extensive foreign assistance. These gains demonstrate that, despite the obvious limits to technical sophistication in all branches of industry, China has developed an effective mechanism for implanting foreign innovations into Chinese industry, for spreading new techniques and products from advanced to backward enterprises and regions, and, in some areas, for devising solutions to uniquely Chinese technological problems.

II.

What can these results contribute to our knowledge of the problem of import substitution and technology transfer shared by all developing economies?

Foreign capital goods typically offer the quickest and cheapest method of injecting new activities into a backward economy. China, for example, could not have begun mass production of tractors, trucks, ball bearings, radios, and a host of other products during the 1950's without massive equipment imports.

Reliance on imported investment goods also has its disadvantages. China is only one of many importing nations which have found it difficult to match local skills, materials, and scarcity relations to the requirements of equipment designed for a foreign economic milieu. These problems often erase at least part of the anticipated advantages of imported equipment and techniques.

More serious is the tendency of a trade-oriented industrialization strategy to curtail the skill formation process which accompanies the search for domestic solutions to technical difficulties. Growth of skill and of the resulting capacity to adapt production to current needs is especially valuable in engineering, the one industry with the potential of supplying all sectors with the means to lower costs and advance productive methods.

Unless domestic engineering producers can begin to display the flexibility which is the hallmark of their advanced-country counterparts, a developing economy runs the risk of finding itself unable to cope with demand shifts too large to be resolved by foreign trade alone. In China's case, only the unanticipated flowering of innovative capacity among older machinery producers prevented such a debacle during the 1960's.

The conclusion to be drawn from this history is that, at some points in the industrialization process, the long-term impact of capital goods imports, which can and do raise the short-term rate of embodied technical progress, may be negative. This possibility arises because imports prevent domestic firms from learning to implement new techniques without purchasing foreign equipment. If exchange stringency or political problems disrupt foreign equipment supplies, domestic capacity to absorb new methods suddenly becomes a constraint on the rate of embodied technical change throughout the economy.

This view, with its emphasis on the long-term benefits of skill accumulation, seems to lie behind the broad Chinese consensus favoring a high degree of national and regional self-reliance in the manufacture of machinery and other producer goods. While accepting imports as a means of breaking technological bottlenecks—recent contracts to purchase eight large-scale fertilizer plants provide an example—the Chinese have kept engineering imports well below 10 percent of domestic output and will probably continue to do so.

Internally, the sequence of repair, parts manufacture, and full production is encouraged in both urban and rural areas. Former repair shops have begun to manufacture trucks, locomotives, and agricultural equipment. Small rural producers of fertilizer, cement, iron, power, coal, and machinery are expected to repair and often even to manufacture their own equipment.

The inevitably mixed results of local self-reliance are tolerated because the Chinese believe that widespread industrial experience will in time reproduce the development sequences which are responsible for the present innovative capacity of older industrial centers. Thus reports of success, as in the thriving factories of Kwangtung's prosperous Chungshan county, alternate with instances of failure, as in Hopei's Kaoch'eng county, where efforts to combat drought foundered because locally produced engines turned out to be useless.

It is difficult to gauge the extent to which Chinese experience and policy in international and internal technology transfer are relevant to the needs of other industrial latecomers. Many nations lack the industrial foundation inherited by the People's Republic; elsewhere, extensive import substitution has failed to stimulate domestic innovative capabilities.

Furthermore, the process by which skill formation extends society's production frontier is both discontinuous and hard to observe, and the resulting innovations can easily elude the economist's productivity measures. Despite these difficulties, the contribution of cumulative industrial experience to China's recent economic gains underlines the desirability of further research into the skill dimensions of industrialization.

TAXATION OF NATURAL RESOURCES

Incidence of World Taxes on Natural Resources with Special Reference to Bauxite

By MALCOLM GILLIS AND CHARLES E. MCLURE, JR.*

Recent increases in taxes on natural resources have focused worldwide attention on the question of their incidence. Who, indeed, does pay these taxes? In the first section we describe a conceptual framework for ordering analysis of the question based on the comparative statics reasoning of tax exporting and general equilibrium incidence analysis. (See McLure, 1964, 1967, and forthcoming.) Section II applies this framework to one concrete case, the heavy production tax Jamaica imposed upon bauxite last summer. Little attempt is made in either section to analyze the fascinating game-theoretic and other dynamic aspects of the mutual adjustment process set off by taxes on natural resources.

I. The Conceptual Framework

The general determinants of the incidence of taxes on natural resources can be presented as in Table 1, though the compartments are not watertight and many nuances are ignored.

The first consideration is whether taxing nations dominate the relevant market for the resource. The relevance of this point is twofold. First, nondominance implies a relatively elastic demand curve for the taxing nation's output, regardless of the industry's demand curve. Second, taxes can be employed to tap resource rents. But if the tax levied by a nondominant country exceeds differential rents resulting from differences in quality and accessability of ore and transportation costs, further exploitation may become uneconomical. (See H. Hughes.) We ignore the possibility of coordinated action by consumer nations.

A second consideration is whether capital is sufficiently mobile to flow from the taxed industry in response to potential reductions in earnings. If capital is mobile, its supply is probably elastic, as seen by the extractive industry in the taxing country (countries). If not, capital—and the accompanying technology—earns essentially quasi-rents. Whether capital is "mobile" depends upon whether we are considering the short run or the long run of economic theory, or, in concrete terms, upon the time phasing of depreciation and maintenance of productive facilities and the level of gross investment in the industry (and, in some instances, upon the nation's exchange control policies). Finally, though we suppress it in Table 1, immobility of labor has implications analogous to those of immobility of capital. But the elasticity of supply of labor depends more crucially upon the possibility of absorbing labor elsewhere in the economy, that is, upon the elasticities of factor sub-

Wells made on earlier drafts of this paper, but to hold them blameless for errors of analysis or interpretation.

TABLE 1—LIKELY INCIDENCE OF TAXES ON NATURAL RESOURCES[a]

I. *Market Dominance* by Taxing Nations	II. *Nondominance* by Taxing Nations
A. Capital Mobile	A. Capital Mobile
Case	Case
1. Competition	7. Competition: resource rents
a. Profits tax: resource rents	8. Monopoly: resource rents
b. Production or export tax: consumers	9. Oligopoly: similar to monopoly case
2. Monopoly:	
a. Profits tax: monopoly rents and resource rents	
b. Production or export tax: one-half by consumers; one-half by monopoly and resource rents	
3. Oligopoly: intermediate between competition and monopoly, depending upon prior success in maximizing joint profits	
B. Capital Immobile	B. Capital Immobile
4. Competition: quasi-rents and resource rents	10. Competition: quasi-rents and resource rents
5. Monopoly: quasi-rents, monopoly rents, and resource rents	11. Monopoly: quasi-rents, resource rents, and monopoly rents
6. Oligopoly: similar to monopoly case, unless joint profits are not maximized. (Shifting to consumers may be possible.)	12. Oligopoly: similar to monopoly case

[a] Applies only to noncreditable portion of corporation income tax. Credited portion borne by crediting nation. Labor receiving higher than competitive wages may share in burdens borne by monopoly and resource rents. Constant costs are assumed to prevail if capital is mobile.

stitution and relative factor intensities in the taxed industry and the rest of the economy.

The third consideration is the industrial structure in the production and distribution of the taxed resource. For simplicity we concentrate upon three traditional descriptions of market structure: competition, monopoly, and oligopoly. Unless the industry is perfectly competitive, there will be monopoly (or monopsony) rents that may be affected by the tax. But this classification does not do justice to the richness of industrial structure observed in individual cases. In particular, the "oligopolistic" characterization tells us little except that there are few firms. In any concrete case we must attempt to determine more precisely how the firms behave, including whether nor not they collude with taxing countries. Thus our conceptual framework is useful in structuring the problem, but is no substitute for detailed analysis.

A final consideration omitted from Table 1 is the prevalence of labor rents. Unionization and industrial concentration often go together, and whether unionization occurs or not, in many cases wages are higher in the taxed industry than in the rest of the economy because of the tendency to equalize, at least partially, wages paid to nationals and expatriates. In either event, local labor shares in resource and monopoly rents.

We can identify twelve cases potentially worth examination, or twenty-four, if we allow for labor rents. Other factors are somewhat different in kind and do not readily lend themselves to taxonomy. First, the incidence of corporation income taxes is more complicated than that of export duties and production taxes. It involves taxation of the return to equity capital as well as economic profits, transfer prices within multinational firms, and, perhaps more importantly, foreign tax credits sometimes available only for income taxes. In general, so long as the taxes in the producing nations do not exceed allowable credits, the credit, made at the expense of taxpayers in the nation granting it, effectively reduces the amount of corporation income tax borne by consumers and recipients of factor incomes.

A second consideration involves whether the contracts typical of the industry can be adjusted to reflect changed fiscal conditions. For our purpose, the "owner" is the party who has an economic interest in the resource over the time period in question, as determined by contractual arrangements, though in many cases the reference may not be legally accurate. That is, he is the one obtaining "resource rents."

If taxing nations dominate the market, other cost and demand conditions become relevant. Substitutes increase the industry's elasticity of demand. Being unimportant—the fraction the resource cost is of total costs—is another crucial determinant of the elasticity of demand. Marginal cost rises more rapidly the less mobile are factors. Beyond that, the quality of the resource and the ease of extracting, processing, and transporting it determine differential resource rents.

The final consideration is a purely mechanical matter. Once we know who—in terms of factor shares and consumer groups—bears the tax, we must allocate the tax to their nations of residence.

Table 1 summarizes the likely incidence of taxes in each of twelve cases. For convenience we assume that if capital is mobile the taxed resource can be exploited at essentially constant costs and that labor outside the taxed sector generally would not share in the tax burden through tax-induced inflows of labor from the taxed sector. Moreover, we suppress repeated mention that labor might share in any reduction of rents. Finally, we distinguish between owners of natural resources (recipients of resource rents) and capitalists exploiting the resources, though in practice the two groups may be virtually identical. Capitalists earn returns to capital (normal returns in the long run; quasi-rents in the short run) and perhaps monopoly profits.

Case 1: Competitive firms subject to production or export taxes in nations dominating the world market would shift the taxes in large part to consumers (except as restrained by substitutes) if capital is mobile. Income taxes would be borne largely by recipients of resource rents, and perhaps by consumers. Its mobility would allow capital to escape the tax.

Case 2: In the constant-cost case a monopolist could shift only one-half a tax on production or export to consumers, the rest being absorbed through reduced monopoly and resource rents. The profits tax would come largely from monopoly and resource rents.

Case 3: The results for oligopoly would resemble those for either competition or monopoly, depending upon how well the firms had done in maximizing joint profits.

Cases 4–6: With capital immobile, either a profits tax or a tax on production or export would generally be borne by recipients of resource rents and quasi-rents of capital and, where relevant, monopoly rents. In these cases, as others, reductions in rents may be borne in part by resident labor, but would ordinarily result in substantial tax exporting. A qualification to this general conclusion is that oligopolistic firms may succeed in shifting part of the tax to consumers if they have not previously maximized joint profits.

Case 7. In this case both the demand for the resource and the supply of capital are perfectly elastic. Thus a tax can neither be shifted to foreign consumers nor reduce the normal earnings of capital. Either a profit or an export or production duty must be borne by owners of the natural resource.

Case 8: The marginal revenue of a monopolist dominating the world market, to which marginal cost in the taxing nation is equated, is determined in the world market. And, by assumption, so is the return to capital. Thus, again, no tax would be shifted forward in higher prices or reduce the return to capital per se. Rather, the burden of a profit, production, or export tax would be borne by owners of natural resources.

Case 9: Again, the results for oligopoly should resemble those for competition and monopoly, namely, burden on resource rents, as in cases 7 and 8.

Cases 10-12: Demand is perfectly elastic, but capital is fixed in supply and therefore earning quasi-rents (and monopoly rents, in cases 11 and 12). Either kind of tax would be borne largely by recipients of various rents.

In summary, then: we expect either profits taxes (in excess of credits) or commodity taxes to be borne largely by recipients of various rents (quasi, resource, and monopoly), including labor, except for the long-run case of a production or export tax levied by nations dominating world markets. If natural resource industries subject to commodity taxes by dominant nations were competitive and substitutes were unimportant, virtually the entire tax might be shifted to consumers. But if monopoly or joint profit maximization by oligopolistic firms prevailed, only about half the tax would be shifted to consumers.

In any event, most countries in which exploitation of natural resources is under foreign ownership could probably export the lion's share of taxes on the resources. First, substantial amounts of creditable taxes are paid by foreign treasuries. Second, if taxing nations dominate the world market, half or more of commodity taxes can be exported to consumers, especially if capital is mobile. Third, reducing the quasi-rents accruing to immobile capital involves substantial tax exporting, at least in the short run. Fourth, monopoly and monopsony rents also accrue largely to nonresidents. Finally, foreigners often effectively own natural resources and would be burdened by any tax that reduces resource rents. The primary caveats involve the sharing of local labor in the reduction of rents and the risk of going so far as to deter future gross investment in the industry, or even in the country.

II. The Bauxite Case

In mid-May Jamaica announced an increase in its bauxite taxes of *U.S.* $170 million per year and the intention to increase Jamaican participation in the ownership of bauxite and alumina operations. (See M. Manley. Bauxite is the principal ore from which aluminum oxide—alumina—is refined for later smelting into aluminum ingot. Total tax receipts in 1973–74 were *U.S.* $357 million; see Jamaica, Ministry of Finance.) Due to the difficulty of determining an arms-length price for bauxite and profits attributable to operations in Jamaica, the tax was levied on production, rather than on profits, and was geared to the price of aluminum ingot. Moreover, it included a presumed minimum level of production of somewhat over 90 percent of estimated production. The Jamaican government doubtless expected the increase in tax to be borne by foreigners. In this section we examine whether this is reasonable.

A. *Dominance*

In March 1974, seven major bauxite-producing nations (Jamaica, Australia, Guyana, Surinam, Guinea, Sierra Leone, and Yugoslavia) established the International Bauxite Association (*IBA*). Indonesia was present as an observer, and in August the Dominican Republic announced its intention to join. (See the *New York Times*, Aug. 14, 1974.) The original *IBA* members accounted for 62 percent of mine production in 1973 and control 63 percent of world bauxite reserves. Australia alone accounts for 30 percent of world reserves, followed by Guinea at 23 percent and Jamaica at nearly 7 percent. In 1973, Australia (23 percent), Jamaica (20 percent), and Guyana (10 percent) were responsible for 53 percent of world mine production (U.S. Department of the Interior, p. 15).[1] Although its members have avoided the "cartel" label and have not yet taken coordinated action, the goals of *IBA* (obtaining higher revenues and developing vertically integrated national aluminum industries) are not atypical of those of cartels, and it appears that the *IBA* could dominate the world market for bauxite if its members acted cooperatively. Meanwhile, three countries supplying much of the North American market have acted consciously parallel, if not cooperatively.

Within two months of Jamaica's unilateral actions, Guyana announced virtually identical taxes,[2] and the Dominican Republic was considering similar measures (*New York Times*, July 11, 1974). In the short term, these three nations enjoy a strong position, especially in their primary markets, even without the support of other *IBA* nations. During 1969–72, they accounted for 68 percent of *U.S.* imports of bauxite, or about 60 percent of *U.S.* mine production plus imports.[3] This fact, and others considered briefly below, suggests that these countries can export a substantial portion of their recent increases in taxes on bauxite. Most obviously, tax exporting to foreign consumers may be possible. This conclusion would be strengthened by concerted *IBA* action. Perhaps equally important, Caribbean deposits enjoy important differential resource rents which can be appropriated through fiscal measures.

Although Jamaican deposits contain only 50 percent alumina (about equal to that of Australian and *U.S.* deposits), they enjoy significant advantages of physical accessibility, silica content, and transport costs. Guyana's deposits are less accessible (owing to a heavy overburden of sand and clay) and transport costs from Guyana exceed those of most other Caribbean producers. However, the alumina content of Guyana's ore (57 percent) is the highest in the world for major deposits, and the country has a virtual monopoly on calcined bauxite (used in the abrasives and refractory industries). Discovery and exploitation of sizable new bauxite fields of comparable quality and accessibility do not appear likely to exert significant downward pressure on differential resource rents of Caribbean deposits through the medium term. The few known large, unexploited deposits are distant from the markets of Jamaica and Guyana and are located in other *IBA* nations, or in nations likely to join *IBA* (Indonesia).

The nature of alumina refining—which involves substantial weight reduction (typically 50 percent)—also generates differential locational rents, above those accruing to bauxite deposits, as such. Recent and projected developments in shipping costs are expected to increase the premia for processing alumina near extraction sites.

B. *Industrial Structure*

Six major producers dominate the international aluminum industry. They control 80 percent of western-world primary aluminum capacity, about one-half of world trade in bauxite, alumina, and aluminum, and a large share of fabrication capacity (R. A. McKern, p. B-72). The six are all fully integrated from bauxite to metal and are active in mining and processing throughout the world, often through joint ventures with one another and with smaller companies. Substantial potential thus exists for monopoly and monopsony rents from Caribbean mining activity. The existence of monopoly rents may, of course, reduce shifting to consumers, but increase tax exporting to nonresident capitalists.

---

[1] Alumina refining is less concentrated in *IBA* countries, and aluminum smelting plants are largely concentrated in developed countries near abundant, low-cost energy sources.

[2] Guyana's tax was set at about 6 percent of the ingot price. Given the higher aluminum oxide content of Guyana bauxite, the production tax per ton of bauxite virtually matched that of Jamaica.

[3] The three countries account for barely one quarter of *U.S.* alumina imports, but the share of all *IBA* members was more than 75 percent from 1969–72 (U.S. Dept. of the Interior, pp. 15–16).

C. *Capital Mobility*

In the short run quasi-rents accrue to the package of factor inputs provided by the firms engaged in the mining of bauxite—capital and the associated technological, management, and often labor skills required for modern, capital-intensive mining. Given the longevity of the substantial amounts of capital invested, (*U.S.* $800 million in Jamaica, for example; see North American Aluminum Producers in Jamaica) the economic short run may well be lengthy, and the appropriation of quasi-rents could be the vehicle of considerable tax exporting. But in the long run the multinational firms can move, especially if the tax policies of the bauxite-producing nations are not fully coordinated. Whether capital is eventually driven out will depend on the success of the *IBA* and whether taxes on bauxite go beyond merely capturing differential resource rents and monopoly rents and encroach upon the normal return to capital and know-how.

D. *Other Considerations*

Ordinary Demand and Cost Considerations

The fiscal measures considered here provide a good example of the importance of being unimportant. Bauxite costs (prior to 1974) typically have been placed at 10 percent of ingot costs (McKern, p. B-76). Therefore, the Jamaican tax increase would, if fully passed forward, raise ingot prices by only about two cents per pound, or by 6 percent, at prices prevailing in July 1974 (International Economic Policy Association, p. 82). Whether a price increase of this magnitude would induce substantial short-term shifts away from aluminum is unclear. The conductivity, strength-to-weight, corrosion resistance, and formability of aluminum suggest not. Costs of replacing aluminum in transport and electrical applications would be particularly high, but substitution would be easy in the beverage and container industry (16 percent of the market). Finally, scrap supplied about 19 percent of total *U.S.* aluminum production in 1970–73 (U.S. Department of the Interior, p. 2). Tax-induced increases in aluminum prices could serve to spur further recycling efforts. This is, however, a quite limited source of supply, except in the short run.

A major concern for the Caribbean members of *IBA* is the longer term displacement of bauxite by other abundant aluminum-bearing materials. The United States is rich in aluminum-bearing clays, such as nepheline synite, and has substantial deposits of alunite, anorthosite, and dawsonite. But the 30 to 38 percent alumina content of these ores is significantly lower than that of most Caribbean and other *IBA* deposits. If the United States were to opt to extract oil from shale, dawsonite would be a sizable byproduct, and could supply the world's aluminum needs for decades. However, potential competition from dawsonite would seem to pose little threat to *IBA* members, at least at present tax levels.[4]

Type of Tax

Because the Jamaican tax presumes a minimum level of production, it is in effect a lump sum tax if production falls below the stipulated level and is truly related to production only when the presumed minimum is surpassed. This feature prevents the majors from holding Jamaica hostage by temporarily shifting production to their mines in other countries and thereby depressing the Jamaican economy. To the contrary, Jamaica in effect is holding the firms hostage. As the tax must be paid whether bauxite is mined or not, the only economical thing to do is to mine at least the minimum amount.

---

[4] On the contrary, if *IBA* members were convinced that the United States intended to exploit its oil shale reserves, they might be well advised to raise taxes on bauxite even further, in order to extract the maximum rents before large-scale generation of dawsonite renders their bauxite deposits worthless.

E. *Summary*

Jamaica and other Caribbean members of *IBA* effectively dominate the North American bauxite market and—except for Surinam—are behaving in a consciously parallel manner. Moreover, the industrial structure is oligopolistic. Thus, in the short run in which capital is essentially immobile, we are dealing with case 6 of our conceptual framework. Over the long run, market dominance may weaken (if the tax renders Caribbean bauxite noncompetitive) or it may increase (if *IBA* becomes a strong worldwide cartel). Thus, in the long run we are dealing with either case 3 or case 9. In case 3 we would expect substantial (say, 50–100 percent) shifting to consumers, and depending upon the behavior of the firms that dominate the world and *U.S.* markets, substantial short-run shifting to consumers might occur even in case 6. Recipients of resource and monopoly rents would bear the remainder of the burden in these cases, and they and recipients of quasi-rents would bear the full burden in case 9. Given consumption patterns and the ownership of the major aluminum firms and Caribbean bauxite deposits, there is little doubt that substantial amounts of the new taxes can be exported in both the short run and the long run, subject only to constraints imposed by weakness of the *IBA* and (if *IBA* proves to be impotent) the level of differential resource rents.

Whether the *IBA* will be a viable cartel is, of course, unknowable. And because of the lack of generally recognized "arms-length" prices for bauxite, it is not possible without further detailed analysis to determine precisely whether the recent tax increases in Jamaica and Guyana have served to fully (or more than fully) wrest away the entire amount of differential resource rent accruing to their deposits. Similarly, owing to the sheer complexities of marketing and pricing and the nature of oligopolistic interaction between multinational enterprises, it is impossible to quantify monopoly rents in mining. But the behavior of one of these firms provides operational evidence that Jamaica and Guyana have not gone too far and, perhaps, that the majors expect the *IBA* to achieve its objectives. Although all the firms operating in Jamaica filed arbitration requests with the International Center for Settlement of Investment Disputes (*ICSID*) immediately after the tax increase, within six months one of the largest of the majors (Kaiser) not only agreed to abandon *ICSID* proceedings against Jamaica, but assented to the government's purchase of 51 percent of the firm's bauxite mining assets. In return, the company will receive a guarantee of reserves sufficient to maintain current rates of extraction for 30 years (*Financial Times*, Nov. 22, 1974). Though Kaiser has geographically less diversified holdings of bauxite than the other majors and is therefore under more pressure to settle, this is nonetheless a significant development.

U. S. Taxes on Energy Resources

By GERARD M. BRANNON*

U.S. tax policy towards energy resources is a pregnant topic. It has an interesting past, an uncomfortable present, and an unknown but promising future. Taxes, however, are not easy to separate from the whole range of government policies.

Ostensibly taxes are concerned with reducing private purchasing power, but their quality is universally measured by how they affect the allocation of resources and the distribution of income and wealth. So deeply are taxes like the whole range of government activities that in recent literature special tax reliefs have been called tax expenditures while a military draft has been described as a tax. In sum, our topic must be taxes and other energy policies.

I. Taxes Past—Pre-1974

Income Tax: The United States lightly taxes income from "producing" natural resources. The benefits from percentage depletion and the deduction of intangible drilling cost and mine development and exploration costs primarily benefit energy resources.

The tax benefits for various fuels as a percentage of the price of fuel delivered to an electric utility vary from 12 to 13 percent for oil and gas to rates of 1.4 to 4.5 percent for oil substitutes (Brannon, 1975). This ostensible discrimination would be acceptable if it could be established that there are inefficiencies in private markets which penalize production of natural resources and that can best be removed by this set of differential tax benefits. We comment on some claims for percentage depletion.

Claim (1). Private markets do not provide adequate incentive to put aside oil and gas reserve productive capacity to be used in future emergencies (because price controls and/or excess profits taxes are likely in emergencies). An extra profit incentive from lower taxes is said to provide a reserve of productive capacity for energy resources (Richard Gonzalez).

Comment (1a). There is little evidence that lower income taxes provide a reserve. Half of the tax benefits are dissipated in higher royalties (Paul Davidson, Brannon, 1974), the remainder providing a drilling incentive. The reserve issue depends on whether new drilling increases productive capacity more than production is increased. Some econometric evidence developed by CONSAD Research Corporation and by Arthur Wright and James Cox concludes that production increases *pari passu* with capacity. It has also been stated by the industry that this is the case (Mid-Continent). The only contrary evidence of which I am aware is that of Edward Erickson, S. Millsaps, and R. Spann, who find some extra reserve creation with a very long lag.

Comment (1b). More direct reserve creation methods are feasible, such as purchase of crude for storage or paying for shut-in reserves (Walter Mead and Phillip Sorenson).

Claim (2). An unintegrated corporate tax works uniquely to the disadvantage of a capital-intensive industry, which because of risk must have a high rate of return (Stephen McDonald, 1970).

Comment (2a). For large oil firms there are sufficient opportunities to spread risk (C. Jackson Grayson), so that negligible risk premium is included in the normal return. Further, a tax benefit increases supply and reduces price, which increases losses of unsuccessful firms while benefiting successful firms. This increases the variance of expected returns, an inefficient remedy for risk aversion. If risk aversion is to be regarded as a social cost to be overcome, the sensible policy would try to reduce risk, e.g., by loss guarantees.

---

* Georgetown University.

Comment (2b). If an unintegrated corporate tax discriminates against capital-intensive industries, and if this result is objectionable, the obvious solution is corporate rate reduction rather than selective relief for industries with political influence.

Comment (2c). Resource extractive industries have a lower long-run elasticity of supply than manufacturing and should, on optimal tax principles, be overtaxed rather than undertaxed (Joseph Stiglitz). The same conclusion is suggested by a general concern that our economic system does not give sufficient concern to conservation. Present tax law discourages using cheaper resources; for any end product the tax burden will be lower the greater the contribution to value added of the resources used.

Claim (3). Existing land-ownership rules make it difficult for a driller to capture the positive externalities of information which result from his drilling. This leads to some underinvestment in drilling, which can be offset by tax incentives (Edward Miller).

Comment (3a). Our land-ownership rules, specifically the absence of compulsory field unitization, result also in a negative externality and overdrilling (McDonald, 1971). There is also a negative externality in that a successful driller reduces the profit prospects of all other drillers by using up some of the limited oil and gas resources (Frederick Peterson).

Comment (3b). Information externalities can be dealt with in other ways, for example, by revising the bidding procedures on public land (Peterson).

Comment (3c). There is a bias toward overdrilling inherent in a tax law which permits a full deduction for dry hole costs. With a 10 percent success ratio, the expected cost of finding a $1 million deposit must be the incurring of $900,000 of dry hole costs. The result is that 90 percent of investment costs in exploratory oil well drilling are recovered for tax purposes within a few years. This is far more generous than the depreciation afforded other twenty-year assets.

My judgment from this argument is that the percentage depletion and the deduction of intangibles on successful wells are unjustifiable.

Another income tax energy issue is the treatment of *U.S.* companies operating abroad under high foreign tax rates. I will accept the principle that the United States should allow a foreign tax credit in the general case of foreign income of *U.S.* companies. Our law unduly favors foreign operations, however, by permitting transfer of excess tax credits on resource income to reduce *U.S.* taxes on lowly taxed foreign incomes and by too favorable treatment of startup losses. The Treasury Department proposals in 1974 dealt adequately with these problems (George Schultz).

Finally, the undertaxation of publicly owned utilities, arising from the absence of an income tax on the utility and its access to tax-free bond financing, unduly reduces electricity prices and increases resource use.

Taxes on Property: U.S. on-shore drilling is subject to severance and property taxes. To some extent severance taxes are substitutes for property taxes but they are also heavier (Allen Manvel). High severance taxes are best explained as an accommodation to the unique feature of *U.S.* property law which designates a landowner as the owner of any oil or gas that comes through a vertical well on his property. A severance tax is a crude effort to recapture a royalty interest. Since the rate does not vary with productivity, it discourages marginal operations and slightly increases prices.

Drilling rights on the outer continental shelf (*OCS*) are sold through competitive bids. This should capture the royalty, but there are questions about bidding procedures, especially the heavy front-end payments (lease bonuses) which limit competition. With the great importance of *OCS* drilling in the future, federal government royalties should recapture much of any long-term tax benefits extended to drillers.

Excise taxes: We pay for highways primarily by taxing gasoline, introducing a slight bias toward economy cars. On a comparative basis our gasoline tax is far lighter than those in other industrial countries. Total automobile and truck taxes fall short of meeting highway costs when one subtracts the revenue that would be collected by imposing regular sales taxes on gasoline. There is also an extensive literature on the inefficiency of highway financing by gasoline taxes compared to a congestion-related tax.

Semi-Taxes—Import Quotas: The United States limited oil imports from 1955 to 1973 when the world oil price was conspicuously below the *U.S.* price. This was equivalent to a tax in that it raised prices on *U.S.* oil, and it was simultaneously like a refinery subsidy since free tickets were distributed to refiners permitting them to buy stated quantities of cheap oil imports (Cabinet Task Force).

The quota system was excessively costly for the benefits derived, and it must have contributed significantly to the development of the Organization of Petroleum Exporting Countries (*OPEC*). A quota tells foreign producers that they get no more sales by reducing prices. If we had been following a reserve inventory program, we could have been in a position to expand purchases from any country willing to follow a large output, low price policy.

Semi-Taxes—Prorationing: The United States limited domestic oil production by a system of prorationing of production days per well. The system was in part conservation oriented but was also directed quite consciously at price maintenance. This, like the quotas, was simultaneously like a tax and a subsidy.

Semi-Taxes—Environmental Controls: The United States has been involved in a heavy-handed program of pollution controls. Like a tax, these controls increase energy costs. The issues involved are whether optimal tradeoffs have been achieved between benefits and costs. Considering the record of government in overestimating benefits and underestimating costs, one cannot tell if the environmental program has involved a net reduction of welfare or not.

Semi-Taxes—Natural Gas Price Regulation: Since the mid-1950's the United States has maintained control on field price on interstate sales of natural gas. Most economists who have dealt with this issue have considered that the price in terms of reduced natural gas development has been excessive as far as any benefits are concerned (MacAvoy and most of the authors assembled in Keith Brown). Regulation operates like a tax, plus a subsidy. It transfers income from producers to consumers.

II. Present Tax Issues

With current oil prices, there is no need to protect a high-cost *U.S.* industry from the rigors of competition. We have responded by trying to hold down prices. The Congress voted to roll back prices but a veto was upheld. In addition to consumer opposition to high oil product prices, there was much pressure for price control from independent refiners and marketers since high profits on crude increase the competitive power of the integrated companies.

The Administration compromised by imposing a ceiling price of $5.25 on old oil (approximately 1972 levels of production in given fields), about 50 percent above the price of a year earlier. Uncontrolled prices were allowed for new oil (increased production) plus a "bonus" amount. One barrel of old oil was freed of price control for each barrel of new production.

There has been only sparring on the tax front. The Department of the Treasury proposed only a temporary excise tax at increasing rates on the part of prices above a base of $4.50, rising to 85 percent on the part above $6.50 a barrel. The tax would phase out over five years (Schultz).

The Ways and Means Committee simultaneously adopted and gutted the Administration's windfall profits (excise) tax, while providing for the long-run phaseout of percentage depletion for oil and gas. The technique for gutting the windfall profits tax was to provide that the tax would be abated to the extent that profits were reinvested in the energy business. Limiting the incentive for energy investment to firms that had ill-gotten gains in the form of "windfall" profits serves to protect the oligopoly position of the major oil producers.

To its credit, the Ways and Means Committee bill provided for a three-year phaseout of the depletion allowance. This led to a maneuver by a group of Committee Democrats to permit a House floor vote on amendments to repeal percentage depletion for oil and gas, effective for 1974, and to eliminate the foreign tax credit on foreign oil operations. The Ways and Means Committee withdrew the oil tax bill and voted to add its provisions to a succession of more general tax reform bills which had not passed at the close of 1974.

The income distribution and resource allocation problems entailed in the massive oil price increase were left to price control, Federal Energy Administration (*FEA*) allocations, and jawbone appeals for conservation. The conservation message is pure noise, which can be roughly translated as "be efficient except where energy is involved, but if energy is involved, maximize efficiency under the assumption that the energy cost is higher than it is. As to how much higher, you guess."

These policies complicate rational energy consumption decisions. The benefit of price control is similar to a cash subsidy which rises with energy consumption. It is higher for the waster than the saver; higher for the rich than the poor. The subsidy involved in price control concentrates the increased demand on the elastic part of supply, imports. Despite official statements that the United States wants a lower world price on oil, *U.S.* policy helps keep the world price of oil up by limiting domestic producers to an average price of $8.50 for a barrel that has a marginal cost of $11.

The economic analysis behind the tax recommendations is a belief that short-run elasticity of domestic supply is low. Presumably the Treasury also believed that in the long run the elasticity of supply of oil was high, which is the implication of the recommendation to phase out the windfall profits tax over a five-year period and is a negative inference from the failure to recommend repeal of percentage depletion.

The elasticity judgment underlying the price control is that even in old wells there is an important potential for growth. A barrel of new oil can be sold at a market price of around $11. Under the Treasury windfall tax scheme, this would have borne an excise tax of about $4.50.

The effort to identify new oil is intriguing but weak (Edward Renshaw). New oil is oil produced on a property in excess of the output in the same month of 1972. This ignores the fact that, with a normal decline rate of about 10 percent a year, special efforts are required to maintain well output. The oversight is roughly offset by the rule which allows each barrel of new oil to free one barrel of old oil from controls. Assuming field output in 1974 would be 81 percent of 1972 output without new recovery efforts, the marginal revenue from oil produced over this base is $5.25 per barrel until output reaches 100 percent of 1972 and then it springs up to $11+(11−5.25) or $16.75 a barrel.

The system is made more chaotic by a Congressional action which removed price ceilings from stripper wells, i.e., wells producing under 10 barrels a day, which account for about 12 percent of *U.S.* capacity.

Continuously, the *Oil and Gas Journal* reports shortages of drilling crews, drilling equipment, oil country pipe, etc. So long as these shortages are significant, there will be little payoff from larger production incentives. For a rough test of the extent of incentive that can pay off, assume the common estimate of an elasticity of supply of 1.0 and note that drilling has increased in 1974 by 20 percent and is expected to increase in 1975 by 40 percent. If we start with a 1972 price of crude oil of $3.50 and adjust it upward for general inflation, it would not have been unreasonable to expect this sort of drilling with the incentive provided by $6 oil. An $11 price is far more than enough to produce the kind of drilling that we have seen.

This strategy shows considerable contempt for elasticity of supply of oil substitutes. The price control faces the oil substitute with an average price of oil of about $8.50, while marginal oil output is rewarded with a price up to $17. This cavalier attitude is not justified by the statement that oil substitutes have environmental problems. With high enough prices, resources can be spent to deal with environmental problems, mine safety, restoration after strip mining, etc.

A rational oil policy would start with eliminating price control. The income problems should be handled by heavier taxes on producers plus redistribution of part of the tax proceeds to consumers in a way that no one gets more for consuming more.

Politically, price control for oil and gas is attractive because it is thought mistakenly that this is the best way to avoid the massive income redistribution from consumers to producers that is involved in large price increases. In economic policy, however, income objectives are far better attained by using income tools than by using price tools.

The first step to increase taxes on producers of oil and gas is to repeal the income tax benefits, percentage depletion, and the current deduction of intangible drilling expenses on successful wells.

It follows from our previous argument about short-run elasticity that an $11 price of crude involves short-term windfalls, i.e., income in excess of the amount necessary to call forth the feasible increase in output over the next few years. As a technical matter, an excise tax on windfall profits could be constructed to parallel exactly the price control of $5.25 a barrel on old oil. A producer should be indifferent between a law that says he must sell an $11 barrel of oil for $5.25 and one that permits sale at $11 with a tax of $5.75.

A little thought could produce a windfall profits tax that would be more efficient than the present price control. Design of an optimum windfall tax would depend primarily on a detailed description of the elasticity of supply. Broadly, the distinction between the new oil and old oil seems useful, although it is our judgment that there is no justification for as large a net difference in the allowable net prices as that provided under present price control rules.

The windfall tax needs to be gradually phased out. In the long run there is, however, an analogous windfall income which would be reflected in royalties. With respect to *OCS* production, this can be recaptured by government bidding procedures for drilling rights. With respect to on-shore production, this is partly recaptured by severance taxes. The latter recapture could be more effective if severance taxes were moderated toward being more precisely adjusted to the royalty on each property, reaching zero on the marginal property—shades of Henry George.

Some very rounded numbers will permit a general quantitative estimate of the revenues under discussion. Domestic crude production is about 3.5 billion barrels a year, 60 percent of which is old oil. I assume the windfall profits tax replicates the producer burden of present price control, although it could be higher. I estimate the values of the present income tax benefits on $5.25 oil are a deduction of 18 percent for percentage depletion and 8 percent for intangibles, and on $11 oil, 20 percent for percentage depletion and 6 percent for intangibles.

The tax benefit in 22 percent depletion is cut down in value by various legal offsets which become less as oil prices rise (Brannon, 1975). Also, at a price of oil of $3, the long-run value of the deduction of intangibles is about half that of percentage depletion (Susan Agria, Brannon, 1975).

The assumptions provide the following revenue gains:

(1) the increased revenue from removing percentage depletion and the intangible deduction on successful wells on 3.5 billion barrels of oil at $11, i.e., (.48)(.26)($11) (3.5 billion) amounts to $4.8 billion;

(2) the windfall tax on 2.1 billion barrels of old oil at $5.03, i.e., $5.75 less differential income tax benefits (2.1 billion)(5.75)(1−(.48)(.26)), comes to $10.6 billion; and

(3) the total is $15.4 billion.

Increased cost to the public for oil would be $5.75×2.1 billion barrels or $12.1 billion. If this much of the revenue were refunded to consumers in the form of a refundable tax credit of $60 a person ($240 for a family of four), consumers on the average would have been made whole. (State experience with refunds of sales and property taxes of the poor show that a program like this is feasible.)

In the long run this refund would have to be moderated to the extent that we had let prices rise above the present price control limits.

The same general approach is applicable to natural gas.

The percentage depletion deduction and the deductibility of certain exploration and development expenses should be terminated for all resources, including the other energy resources coal, uranium, and geothermal steam.

III. Future Taxes

With the present high world price, Project Independence has captured the imagination of the public and the politicians alike. There are a number of plausible concepts of energy independence, such as (1) a zero level of imports and (2) reserves adequate to cover imports reduced by a feasible level of reduced consumption.

Before I comment on the choice of policies, note that concept (1) could be defined equally well by the expression "*OPEC* pricing itself out of the American market." If this occurs, the independence problem solves itself. At present world oil prices, this seems plausible. If we adjust the pre-embargo *U.S.* oil price of $3.50 generously for inflation to put it at $4.50, the current import price is about a 150 percent increase. As of 1972, standard long-term projections were that the United States would provide about half of its oil supply in the 1980's (National Petroleum Council). It is also estimated that the long-run supply elasticity is about 1.0 (Henry Steele, Schultz). Assuming this historical elasticity prevails in the future, *U.S.* production should double and fully replace imports. Extrapolation is hazardous, but there is good reason to expect that at prices of $8 to $10 new supplies from shale, or coal liquefaction, or expanded nuclear energy could increase supply elasticity at high prices. At an $11 price, there should be significantly less oil demanded. Long-run demand elasticity has been estimated at 0.5 (J. C. Burrows and T. A. Dommenich).

While independence is plausible even without special government policies, the prospect left out of account is the *OPEC* cartel strategy. A substantial development of alternate energy sources in the United States, Europe, and Japan should push the cartel to a lower price strategy.

If we develop alternate *U.S.* sources to provide a substitute for high foreign prices, the foreign prices are likely to come down, leaving the expanded *U.S.* industry in a depressed state that cries for protection. If the prospects of future losses from lower foreign prices deter *U.S.* development, then lower foreign prices will not materialize.

The present *U.S.* policy position is an odd combination of heavy subsidies for research and development on alternate sources, principally nuclear, plus a price control position on oil that, as we noted earlier, provides generous marginal prices for oil development but abnormally low average oil prices to deter current development of all nonoil substitutes.

At this point, a most effective form of intervention would seem to be one that goes to the problem of prospective losses from future reductions in world oil prices. A constraint on this policy should be, however, that the problem be solved in a way that will not deprive *U.S.* consumers of any advantages that might accrue from lower world oil prices.

This specification does seem to eliminate the kind of oil import quota that we maintained in the period of the 1950's to 1973. A sensible kind of policy would seem to be one that was willing to accept oil imports at any time. If unreliable imports create security problems, then a contingency reserve should be maintained, financed by a tax on imports. The added security is a service provided to users of imports and represents a real cost that importers should pay. The size and character of a contingency reserve would have to be determined from a probability evaluation of various interruption scenarios. It is commonly asserted that a reserve equivalent to one year's imports is adequate, and this would involve a continuing cost of $1 per barrel. (Mead and Sorenson). The cost is annual interest and maintenance, so a continuing import tax is needed.

A strategy for building up this reserve could be an open-ended offer to buy in bulk from any producer country that would make a significantly lower price available.

Beyond this contingency reserve financed by import taxes, we have to encourage development of alternate sources to "break" the cartel. The *U.S.* government should deal with this by minimizing prospective losses to producers of substitutes, but this should be done economically. This suggests that the *U.S.* commitment be limited to a loss guarantee provision similar to provisions built into war procurement contracts to cover a sudden end of the war. The loss guarantee should be designed to cover the part of fixed costs that could not be covered by continued operation in the face of future imported oil prices (that would include the security tax of about $1). Unlike a subsidy in the form of a return to oil quotas, the loss guarantee policy would be designed to cover only sunk costs and not to encourage continued operation of high-cost domestic substitutes that would involve mounting losses.

Project Independence must be designed so as to avoid its becoming an old-fashioned protective tariff.

DISCUSSION

ARTHUR W. WRIGHT, University of Massachusetts: Both the Gerard Brannon and the Malcolm Gillis-Charles McLure papers illustrate the point that we cannot deal adequately with the taxation of natural resources in isolation from alternative, nontax policy measures. By recognizing this point, Brannon is able to put energy taxes in proper perspective and to suggest interesting interpretations of nontax policies (e.g., the oil import quota). In contrast, by focusing on tax incidence in isolation from other, more basic policy issues, Gillis and McLure do not fully exploit the potential of their topic.

It is appropriate to begin the discussion of Brannon's paper by indicating substantial agreement with his treatments of (1) the percentage depletion allowance and the expensing of "intangible" drilling and dry-hole costs; (2) the price controls on domestic crude oil and natural gas; and (3) the proposed loss-guarantees for high-cost alternatives to *OPEC* oil. There is less agreement on foreign tax credits.

To me, the most interesting part of Brannon's paper is his treatment of a windfall profits tax on oil and natural gas. As a preliminary, we can improve upon his definition of "windfall income." According to that definition, firms would realize windfall profits only when they were operating along the perfectly inelastic portions of their supply schedules. In fact, windfall profits can be said to arise from any unexpected increase in market price. The quarrel here is more than semantic: under Brannon's definition, nothing varies but the distribution of the windfall rents, whereas under the broader definition attempts by governments to appropriate those rents may affect market price and quantity—that is, the efficiency of resource allocation. Unless we want to discuss Alfred Marshall's "market period" case (and no bureaucracy, let alone a legislature, could ever move fast enough to appropriate market-period rents), in the interesting cases both demand and supply will have finite, nonzero slopes.

The windfall profits excise tax measure proposed by the Treasury, which Brannon apparently favors, would raise price and reduce quantity compared to the no-tax equilibrium. In the familiar story, the resulting tax revenues and deadweight loss would be borne by both consumers and producers. When the Treasury first mooted its proposal, the *OPEC* cartel and the Arab embargo had already inflicted upon consumers some deadweight loss and transfers of wealth to foreign and domestic producers; the Treasury's excise tax would compound both the inefficiency and the redistribution of income away from consumers. The tax revenues could, of course, be rebated to consumers, as Brannon recommends, but the added inefficiency would remain.

By the rough numerical estimates presented at the end of section II of Brannon's paper, consumers could be more than compensated out of tax revenues for the increase in price resulting from the excise tax. This result is, however, specific to the particular assumptions made in the calculation (which may be suggestive but is too rough to serve as the basis of a major policy initiative).

Brannon advocates gradually phasing out a windfall profits tax according to a definite timetable; however, he dismisses too cavalierly the possibility that such a scheme would induce destabilizing intertemporal shifts in supply. It would be worth exploring whether uncertain timing of tax reductions might not prevent or discourage such shifts. (This is not an argument for the Brownian motion of statements and retractions which passes for energy "policy" in the Ford Administration.) Interestingly, it would also be worth exploring whether an announced timetable for phasing out percentage depletion and the special expensing provisions for oil and gas corporate income might not give an added incentive to produce more petroleum now, thereby easing the present burden on consumers *and* cutting windfall profits in the industry. In the topsy-turvy world of the energy crisis, no paradox is implausible.

The foregoing analytical complexities, plus the apparent impracticability of differentiated taxes on economic rents, suggest that it is not self-evident that "a little thought could produce a windfall profits tax that would be more efficient than the present price control." This may explain why governments so readily resort to price controls. Not that controls are the right answer, as Brannon persuasively argues. But why not then (as he also argues) rely on income tools rather than price tools to attain income objectives?

The possibility of an *OPEC*-like cartel in the world market for bauxite is a highly interesting subject. Unfortunately, Gillis and McLure focus on a relatively uninteresting aspect of that subject: the incidence of any taxes which Jamaica and other bauxite-producing countries may impose on the aluminum companies is distinctly not the focal issue in the world bauxite market. Thus their framework for analyzing tax incidence, which occupies the first half of the paper and which I find confusing and cumbersome rather than helpful, is not really used in the second half of the paper on Jamaica's new bauxite tax. This latter section of the paper is tantalizing but, in the end, not satisfying.

The central issue can be posed quite simply: *without* a world bauxite cartel, Jamaica and other members of the International Bauxite Association (*IBA*) can appropriate at most the total rents accruing to producers in a competitive market; *with* a cartel, however, they can appropriate all that and much more—namely, monopoly rents at the expense of consumers and world economic efficiency. Assume for simplicity that foreigners now own all the rights to Jamaican bauxite, and that Jamaicans now consume a negligible proportion of world output of aluminum products. Then, without a cartel, Jamaica can tax away (or otherwise secure) producer rents at the expense of the current foreign owners. With a cartel, however, Jamaica will be able to reap in addition a transfer of wealth from foreign consumers of aluminum products and also to foist upon the non-bauxite-producing world some amount of deadweight loss. So much for the "incidence" of different pure cases in the bauxite market; the interested reader can lay out the mixed cases on his own.

The crucial question here is whether the *IBA* will follow successfully in *OPEC*'s footsteps. Gillis and McLure give us several clues in the second part of their paper, although we still lack sufficient information to answer that question with confidence. The structure of the new tax—the stipulated minimum output and the tie to ingot prices—is reminiscent of the "posted prices" used to compute the tax liabilities of the oil companies in the Middle East. The early capitulation of Kaiser Industries (and, most recently, of Alcoa in Surinam) is reminiscent of the cooperative attitude of the oil companies towards *OPEC*'s price increase goals. Yet a nagging doubt remains that there are too many competing sources of alumina, over too wide an area and under too numerous a set of jurisdictions, for the *IBA* to achieve and maintain the internal discipline displayed to date by the largest oil exporters in *OPEC*.

Gillis and McLure hint at a number of other possible paper topics, some of them involving tax issues, dealing with the world bauxite market. For example, assuming no cartel, what set of taxes or other policy measures (e.g., nationalization) should Jamaica adopt in order to appropriate the maximum producer rents? What set of individual and joint measures would maximize the *IBA*'s chances of forming a cartel? What does the possibility of a bauxite cartel imply for *U.S.* policy towards oil shale, which contains the low-grade source of alumina, dawsonite, and which is also affected by the *OPEC* cartel? Should, or can, the United States alter its foreign tax credit laws to prevent the *IBA* from siphoning off rents which could go to the U.S. Treasury? One's appetite is whetted, but the plate is, as yet, still empty.

OPTIMIZING MODELS OF PUBLIC DECISION MAKING

Purposive Models of Legislative Behavior

By JOHN A. FEREJOHN AND MORRIS P. FIORINA*

Although political scientists have studied Congress and other legislative bodies for many years, they have been relatively unsuccessful in developing a general theory of legislative behavior. Picking and choosing from the conceptual stores of sociology and psychology, political scientists have organized their research around concepts such as role, norm, integration, etc. Almost without exception the resulting partial theories are quite vaguely formulated, so that one cannot determine which propositions strictly derive from the theory. In other words, though we have good descriptive information about how certain legislatures work, we have a very limited set of theoretical propositions that can help to explain these workings. Still, some scholars appear to have excellent intuitions about how alterations in various internal or external institutions affect the operation of legislatures and their policy output. Thus, we believe there is a deeper understanding of legislative behavior than the lack of a theoretical superstructure suggests.

In recent years several developments have shown some promise of filling the theoretical gaps in the study of legislative behavior. First, game theorists and social choice theorists have begun to formulate abstract models of simple legislatures. Thus we now have a short but growing list of propositions about legislative behavior and policy making in certain highly simplified situations. Second, some empirical researchers have gradually become aware that legislators are goal-seeking agents who choose from available strategic alternatives to further their ends. Some recent empirical work reflects this realization. Third, a number of scholars have been working to bridge the gap between highly abstract social-choice and game-theoretic models of legislatures on the one hand and detailed empirical studies of legislatures on the other. In this necessarily short review we will provide a brief survey of the work underlying each of these developments. The discussion which follows proceeds in stages from the abstract constructions of the game theorists to the more concrete descriptions of empirical researchers.

I. Game Theory and the Legislative Process

Since the publication of *The Theory of Games and Economic Behavior*, several authors have proposed simple game-theoretic models of legislatures. In this section we describe the basic elements of such models and discuss the kinds of propositions they imply. Game-theoretic models typically have a set of *actors*, each of whom have *preferences* defined over a set of "alternatives" or "social states." These preferences are usually assumed to satisfy certain rationality properties. Subsets of the set of actors are called *coalitions* and coalitional preference is usually defined as follows: coalition is said to prefer x to y if and only if each of its members prefers x to y.

A principal notion in game-theoretic

---

* California Institute of Technology.

analysis of legislatures is the idea of coalitional power. One way to formulate this notion is as a characteristic function. The characteristic function is a mapping from coalitions into subsets of the alternatives, which specifies for each coalition in its domain the alternatives that coalition can enforce (S. D. Bloomfield and R. B. Wilson). Another way of conceptualizing coalitional power is a set of binary *effectiveness* relations, one for each coalition, which describe for each coalition its ability to determine the outcome of the legislative process on pairs. That is, if a given coalition is effective for x against y, then it can ensure that if the legislature is choosing between x and y, x will be chosen. A game is simply the set of players and the set of alternatives together with a list of permissible or formable coalitions and some description of the powers of the formable coalitions.

The three elements introduced thus far (*preferences* held by the members, formable *coalitions*, and *powers* of each of the formable coalitions) enable us to make some statements about what a legislature will do when faced with particular choices. One can define a dominance relation as follows: x dominates y if and only if there is a permissible coalition that can ensure x and which prefers x to y. In the next section we will review the work of a number of scholars who have placed sufficient restrictions on the distribution of legislator preferences to ensure the existence of an undominated element. As is well known, however, without such restrictions many legislative institutions cannot be counted on to produce a dominance relation which has an undominated element. This has led some scholars to theorize about what will happen if no undominated element exists.

Several authors have developed solution concepts that allow one to make assertions about what will happen in games without undominated elements (G. Owen). Unfortunately, the solution concepts advanced thus far typically do not make very strong statements about the outcomes of a game. In many games of interest the solutions constitute a very large set relative to the set of possible outcomes.

As a result William Riker suggests that while we may be unable to predict what alternatives will be chosen in a given legislative situation, we may be able to make assertions about which coalitions will form and/or remain stable. He proposes a rule—the size principle—which asserts that in constant-sum games of perfect information only minimal-winning coalitions form. This principle has received careful attention from theorists (Robert Butterworth, Kenneth A. Shepsle 1974a, 1974b, Richard McKelvey), but its status as a theoretical proposition remains ambiguous. For, except in noncontroversial cases in which an undominated element exists, each alternative is dominated by some other, so that even if a minimal-winning coalition moves the legislative from y to x, another coalition could move the legislative from x to z. In general, one cannot expect coalitions to be stable. Perhaps Riker is using the notion of coalition formation in a somewhat different sense than is natural in a game-theoretic terminology. One might define a somewhat different concept of coalition formation and argue that even when the domination relation is cyclic only minimal-winning coalitions form. Recently McKelvey has shown that, if a certain restriction is placed on the payoff configurations that are admissible, a version of the size principle follows. As a descriptive principle, however, the condition McKelvey proposes is dubious.

A number of political researchers have conducted empirical studies to see how accurate the size principle is as a descriptive hypothesis. Some examples are those by David Koehler, Barbara Hinckley, and David Moore. None of these authors finds a pronounced tendency for minimal-winning coalitions to form in legislative voting behavior. Thus, the size principle does not appear to describe legislative coalition formation, at least as measured in these studies. Nonetheless, despite its limited theoretical and empirical support, many scholars (of both theoretical and empirical inclinations) find the size principle intuitively appealing.

II. Spatial Models of Legislatures

In spatial models of legislatures the set of alternatives is assumed to be a subset of Euclidean space, and each legislator is assumed to have a most preferred point within the subset. Legislator preferences may be positively monotonic in distance (Duncan Black), convex, and representable by a differentiable utility function (Charles Plott), convex (Judith Sloss), and/or separable (Gerald Kramer). The basic idea of this type of models is to provide conditions on preferences sufficient to ensure the existence of an undominated point in the set of alternatives.

Black proves that if preferences are convex (i.e., single peaked) in a one-dimensional Euclidean space and if each person votes for the alternative he prefers in each pairwise contest, then there is an alternative (the median position) that cannot be defeated in a pairwise majority vote. As is well known, if the dimensionality of the space exceeds one, convexity is no longer a sufficient condition for the existence of an undominated element.

Plott provides a set of sufficient conditions for the existence of an undominated element when the set of alternatives is a subset of an n-dimensional Euclidean space, and each voter has a concave, differentiable utility function on the set. Plott's condition roughly may be stated as follows. If there is an odd number of voters and they are arranged in a subset of Euclidean space in such a way that one voter is located at an interior point, x, then x is an undominated point if and only if for each utility gradient pointing in a given direction there is another pointing in the opposite direction. Sloss generalized Plott's theorem to weaken the requirement that voters have differentiable utility functions. She requires only that voter preferences be quasi-transitive and satisfy a certain convexity property. In her work convex cones with "gradientlike" properties play much the same role as the gradients in Plott's theorem.

Kramer extends results of Black, A. K. Sen, and others to the case of a multidimensional space of alternatives by giving a class of sufficient conditions for the existence of an undominated element. He argues that the class of conditions which he and Plott provide are so restrictive they are "unlikely to be satisfied in practice except by care and lucky accident" (Kramer 1973, p. 296).

In another contribution Kramer (1972) shows that if legislators have convex and separable preferences over a subset of an n-dimensional Euclidean space, if motions to amend the status quo, x, can change the status quo in at most one component (i.e., issue) at a time, and if legislators vote for a motion if and only if they are made better off by its passage, then there exists a point which is undominated. That is, if legislators do not cooperate too extensively in making their voting decisions, the rules restricting the agenda may create undominated elements. Of course such procedural devices will be ineffective if legislators coordinate their voting strategies sufficiently. Nevertheless, such coordination may be costly enough that the conditions of the theorem are sometimes met in practice.

III. Vote Trading

Some authors have suggested that vote trading is a desirable activity in legislatures and that it may lead to outcomes socially superior to sincere voting outcomes (James Buchanan and Gordon Tullock). Numerous papers on vote trading have been published, but one finds a notable lack of consensus among their authors both on definitions and conclusions. The most important accepted result is the following: if any trade may occur among legislators, and if legislator preferences are separable, a point, x, is an equilibrium in the vote-trading process if and only if it is the outcome of issue-by-issue voting with no trades occurring. Of course the trading process may have no equilibrium. (See Koehler 1975, Peter Bernholz, Joseph Kadane, and Ferejohn 1974b.) The basic idea of the proofs is simply that if any coalition may be organized costlessly to carry out a trade, and if the ultimate decision rule is the method of majority decision, then informal or formal institutions may always be circumvented by an appropriately organized majority. Only to the extent that trades are costly to implement and to police can formal or informal institutions create undominated elements where none would exist under simple majority rule with sincere voting.

We think that this observation may be of considerable importance in understanding how an institution like the Congress works. The Congress is not merely a bicameral body with decisions in each house made by simple majority rule. Rather, there are a number of formal and informal institutions (the committees, the parties, the state party delegations, the leadership systems, the policy groups, etc.) which hold more or less regular places in the legislative process. The presence of such institutions makes some coalitions cheap to organize and others much less so. Differential organization costs may affect not only the existence of equilibria, but also the distributive consequences of policy outcomes (Ferejohn, 1974a). While little theoretical or empirical work has taken place along these lines, it appears that members of certain institutions within the Congress have distinct advantages with respect to particular legislative outputs. The existence of regular distributional effects is difficult to explain without some notion that certain coalitions are more difficult to form than others (namely those that could upset the allocation in question).

IV. Models of the Committee Assignment Process

While legislation may be proposed and amended on the floor of either chamber of the Congress, in practice this almost never happens. Instead, a proposed bill is referred to a committee, which then decides whether the bill will be reported to the whole chamber and, if so, in what form. As a rule, few amendments are offered on the floor (although committee to committee variation is wide) and even fewer are successful. But although most of the policy output of the Congress is determined in committee, little attention has been devoted to incorporating the standing committee system into models of the Congressional process. Recently, however, theorists have focused on one aspect of the committee system—the assignment process. Using simple optimizing models they can successfully account for most of the available data about Congressional committee assignments. Unlike models which require only that legislators be rational agents (i.e., that they be maximizing *something*) the assignment models postulate a specific objective function which the Committee on Committees tries to maximize.

The assignment process operates as follows. Newly elected Congressmen and those dissatisfied with their current assignments submit requests to their party's Committee on Committees. These requests take the form of partial rankings of the committees of the House. The Committee on Committees then meets to consider these requests and make the actual assignments. There are some formal restraints on assignments: all members must receive a committee; members may be placed on one exclusive committee, or on one semiexclusive and one nonexclusive committee, or on two nonexclusive committees. Additionally, the descriptive literature identifies various informal constraints on assignments: no freshmen on exclusive committees; reserved seats for certain states on certain committees; higher priority for nonfreshmen requesters than for freshmen.

In Shepsle's (1975) model of the assignment process, both the informal constraints and the ranking information about requests are omitted. Instead, Shepsle assumes that the Committee on Committees maximizes the number of requests satisfied. Using data only for freshmen requesters and for the Democratic Committee on Committees for four Congresses, Shepsle finds that this extremely simple model accounts for "most" of the assignments in the following sense: while it might be possible to satisfy a few more requests by rearranging assignments, the number of feasible assignments is so large and the search costs sufficiently high that the actual assignments seem a reasonable approximation to the optimum.

Michael Cohen's model employs a similar objective function. Interestingly, the Committee on Committees allegedly considers the committees in alphabetic order. After studying the consequences of various sequential assignment methods, Cohen concludes that quite different assignments would result if assignments were considered in other sequences.

The relatively good fit of the Shepsle and Cohen models suggests that committees are made up largely of self-selected members. Farm state Representatives migrate to Agriculture; Western Representatives gravitate to Interior. Given that the committees exercise a great deal of influence in writing legislation, the end result is a situation in which policy advocates write public policy for the whole Congress. In an interesting work William Niskanen examines the consequences of a system in which committees dominated by program advocates write legislation; he concludes that such a system has undesirable allocative properties. Ferejohn's (1974a) empirical study of Congressional policy making in the area of water resources supports Niskanen's conclusions.

V. Models of Roll Call Voting

One of the most conspicuous aspects of legislative behavior is the roll call vote. The voting records constitute a happy hunting ground for statistically oriented political scientists, and a few models of the vote decision now exist.

Duncan MacRae first proposed a model of roll call voting. The model is theoretically quite ambitious: it attempts to integrate a spatial model of electoral behavior in the constituency with a spatial model of roll call voting in the legislature. Representatives do not simply take the median position of their districts in this model because their votes depend on their personal policy preferences, their electoral margins, and the overall "political complexion" of their districts, in addition to their constituents' approval and disapproval. Given the relative complexity of the model, general results are somewhat hard to come by.

In another contribution, Fiorina (1974) views Representatives as using their vote either to maximize their probability of reelection or to maintain it at some personally satisfactory level. In this model Representatives make decisions under uncertainty about the likelihood that their vote will elicit an electoral reward or punishment of a given magnitude. The homogeneity of a district's group structure emerges as critical in Fiorina's model. Optimal roll call voting strategies always exist in homogeneous districts, but not in heterogeneous districts. Other propositions in the model concern the effects of (1) variations in rewards and punishments stemming from votes, (2) the likelihood a vote will become a campaign issue, and (3) abstention.

In contrast, Jane Gilbert offers a decision-making-under-certainty model of Congressional roll call voting. She assumes Congressmen desire only 50 percent $+\epsilon$ of the vote. In the model, this limited electoral objective frees them to cast other votes with party leaders in order to build up credit within the institution. The number of free votes Congressmen have depends on two dimensions of district heterogeneity: consensus and diversity (the former refers to agreement on a single roll call, the latter to agreement across a series of roll calls). Interestingly, Gilbert's conclusions about the effects of district heterogeneity directly contradict Fiorina's. In the Gilbert model, Congressmen wish to have diverse districts—they should be willing to ask state legislatures to redistrict them out of safe, homogeneous districts. This startling difference between the two models stems largely from the differing candidate-objective functions assumed. In Gilbert's model candidates strive to get only one vote more than a tie. If ϵ were set higher, say 10 percent, the conclusions of the Gilbert and Fiorina models would be similar.

VI. Mainstream Political Science and Optimizing Models of Congress

Of the models thus far discussed, only a minority have been the creation of political scientists. As a discipline, political science has been influenced far more by sociology and social psychology than by economics. Research on Congress, in particular, is organized around concepts such as "role," "norm," and "socialization" rather than "preference," "choice," and "maximization." But, very recently, mainstream Congressional scholars have given strong indications that they are broadening their collection of intellectual tools.

For example, Richard Fenno presents a large-scale comparative study of Congressional committees within the framework of a purposive analytical model. Fenno sees Congressmen as desiring reelection, good public policy, and institutional influence—different mixes for different Representatives. The committees, in turn, offer differing opportunities to satisfy these differing goals (e.g., Public Works or Interior are clearly more valuable for electoral purposes than Foreign Affairs). Fenno argues that Congressmen's goals affect the committee assignments they seek and, in conjunction with the political environment, the formal structure and informal procedures of the committees.

Other empirical works which show the utility of purposive models of behavior include James T. Murphy's analysis of the House Public Works Committee decision making, John F. Manley's study of the House Ways and Means Committee, Barbara Deckard's analysis of state delegations in the House of Representatives, David Rohde's and Shepsle's examination of committee requests in the House of Representatives, John Kingdon's excellent study of roll call voting decisions, and David Mayhew's interpretative review of the Congressional literature.

Empirical research on legislatures has yielded more than detailed descriptions of Congressional institutions, processes, and behavior. It also has provided a growing list of regularities which seem sturdy enough to bear close theoretical examination. Some of these observations are as old as the hills, but receive support from recent work as well: the work of the Congress is done in committees; committee decisions are seldom overturned on the floor; party membership is the single most important predictor of roll call votes; certain committees (such as Appropriations and Ways and Means) are consistently more successful on the floor than are others (Education and Labor or Agriculture, for example). There are other such propositions which could be culled from an examination of the empirical literature. To a surprising extent these propositions appear to hold not merely in the House and Senate, but also in many state legislatures as well.

The existence of empirical regularities in a relatively wide variety of legislative situations (across time as well as cross-sectionally) is a challenge to theorists. What is it about legislative bodies that makes committee decisions tend to remain stable during floor consideration under simple majority rule? The empirical literature on Congress indicates not only that seemingly undominated alternatives exist, but that these alternatives regularly emerge as committee bills. The theoretical literature suggests that this is an extraordinarily improbable state of affairs. Surely we should search for an explanation of this phenomenon.

In our opinion, the theoretical literature on legislative bodies is sufficiently advanced that we may begin to hope for answers to the preceding kind of question. One would hope that over the next few years theorists will take the body of empirical research seriously enough to attempt to provide explanations for observed regularities, and simultaneously to provide a theoretical base for future empirical research.

An Evolutionary and Institutional View of the Behavior of Public and Private Companies

By MARC J. ROBERTS*

This paper reports on an extensive study designed to explain the variations both within and among three public and three private electric utilities in their impact on environmental quality. The more general purpose is to demonstrate the value of a disaggregated model of the behavior of an organization based on the intendedly rational, but imperfect, choices of its individual members. The analysis focuses on what determines the opportunity sets, objectives, and beliefs of those members and on how the organization aggregates their choices into corporate patterns of action. Internal features of the organization—such as how tasks and authority are divided, information processed, and individuals recruited and rewarded—are thus potentially important explanatory variables, provided (as is often the case) that external pressures and constraints are not perfectly coercive.

This conceptual framework would appear to be applicable to a wide variety of public, private, and nonprofit organizations, while generating a number of the better known models of firm behavior as special cases. It is designed both to provide a framework for constructing explanations of particular past events and to give rise to testable generalizations about the behavior of organizations—particularly ones that might be useful for policy purposes. This necessarily brief paper presents only the general arguments and results, with illustrations from the case material. Since the case studies suggested much of the theoretical analysis, they do not provide strictly independent support for the propositions to be presented. (For a full account see Roberts 1975.)

I. Conceptual Framework

Real organizations do not maintain continuous, perfectly calibrated control over all their activities in order to insure "optimal" outcomes. As Herbert Simon and others (e.g., William Baumol and R. E. Quandt) have taught us, doing so is often impossible, and in any case it is generally not globally rational; the gains of perfect over imperfect decisions are typically not worth the added costs. Instead, "satisfactory" solutions are sought to a series of "problems" as these are generated by changing external circumstances, bureaucratic routines, or the poor performance of the organization in the eyes of its members.

Within the organization, the structure of tasks and authority transforms each corporate problem into a set of decision problems for each member and then combines the individual choices which result into a pattern of collective action.[1] An individual's impact on this process will depend upon, among other things, the resources and information channels he controls, his influence on others, and on how much he tries to influence each particular outcome. For the organization as a whole, the consequences of its actions will in turn depend on the responses of various external actors (competitors, buyers, regulators) and on the nature of the organization's relationship to them.

---

* Associate professor of economics, Harvard University. I am very grateful to William Capron, Richard Caves, James Duesenberry, Otto Eckstein, Richard Neustadt, and Thomas Schelling and to the participants in seminars at Harvard, Columbia, and Princeton for their comments on earlier versions of this and related papers, and to the Ford Foundation for supporting this research. The administrative and secretarial assistance of Lois Hager, the research assistance of Lane McIntosh, and the collaboration of Jeremy Bluhm on the larger study on which this paper draws have been essential to the project.

Each organization member has certain control variables such as his own time, a budget, the time of his subordinates, and so on, and certain target variables such as his immediate financial gain, his professional status, his future career prospects, etc. The various processes and practices within the organization that connect an individual's control and target variables can be thought of as a control and incentive system.[2]

For top management, the ideal control system would shape individual opportunity sets so that, in pursuing their own goals, the members of the organization make decisions that lead to the corporate actions and outcomes which top management desires. In practice, however, organizational perfection (like analytical perfection) is either infinitely or at least unattractively costly. Hence more or less crude performance indexes, output quotas, input restrictions, or other devices are often employed. The effectiveness of any control system is also limited by the fact that some individual target variables may be partly or wholly beyond the reach of the control system (e.g., the wish to exhibit technical virtuosity or a desire for world peace).

This account suggests that we can view the structure of the individual's decision problem in the manner illustrated by the flow chart in Figure I. Leaving aside some of the connecting arguments for brevity, suppose that individuals are intendedly but imperfectly rational in pursuing multiple objectives and that those objectives and beliefs about how to achieve them are influenced by past experience. Then the following four classes of variables should serve to explain how individual choices are made within organizations and then aggregated into patterns of corporate behavior.

The external environment of the organization includes the factor and product markets in which it operates, the regulatory constraints upon it, and the social and political pressures to which it is subject. These determine the consequences for the organization of its actions and hence partly define individual opportunity sets as well since individual rewards will often depend, to some extent, on what happens to the organization as a whole.

The organizational structure defines the tasks each member faces and the resources he controls to carry them out. This category includes the way authority is delegated, information communicated, and the responsibilities, size, and scope of various functional units.

The control system includes all personnel, promotion, and compensation practices that mete out rewards and punishments to members of the organization as a result of their choices and behavior. Along with the external environment and the organization's structure, it determines each member's opportunity set.

---

[1] The discussion which follows obviously owes much to James March and Simon, Alfred Chandler, and Joseph Bower. It differs from some so-called "behavioral" analyses in that it seeks to reproduce the decision problems of particular individuals and not simply the implicit logic in the firm's behavior. Compare Richard Cyert and March, chs. 7 and 8. A more complete discussion of the model here is given in Roberts (1975). A somewhat related work is O. E. Williamson.

[2] Thus, our analysis differs qualitatively from various comparative static models of cooperative and collective enterprises, which have assumed that all members confront a similar and unchanging relationship between corporate and private outcomes. See among others Jaroslav Vanek, M. Pauly and M. Redisch, and Joe S. Bain, Richard E. Caves, and Julius Margolis, pp. 276ff.

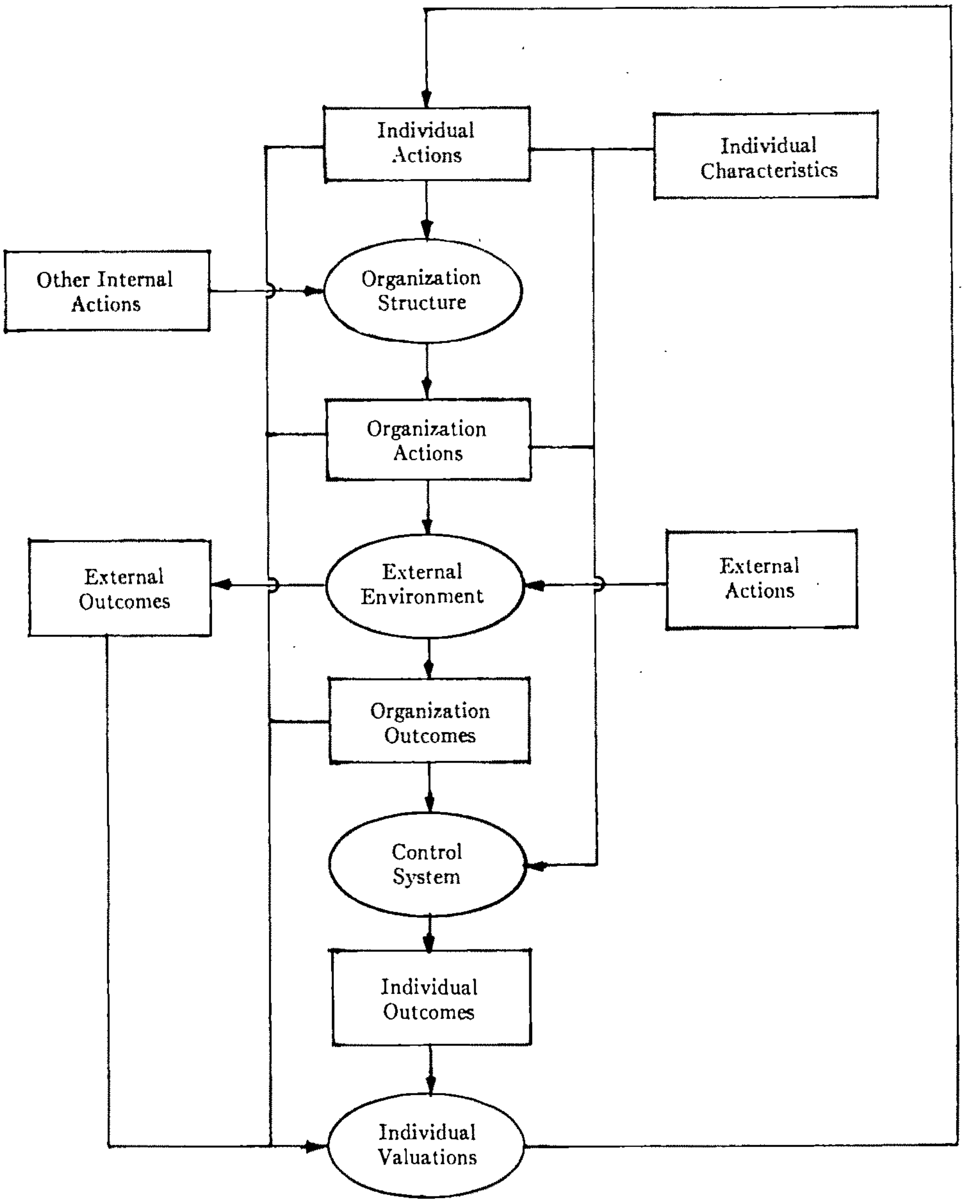

FIGURE 1: THE STRUCTURE OF AN INDIVIDUAL ORGANIZATION MEMBER'S DECISION PROBLEM

Individual objectives and beliefs, in turn, determine how the members of the organization respond to the decision problems which the organization poses to them. The beliefs held by others are also an important aspect of each individual's opportunity set. Such beliefs include personal and professional norms, beliefs which are distinctly characteristic of most organization members (which I will call the *organization's ideology*), and the plans and approach to business problems chosen by top management (which can be called the *organization's strategy*). The distribution of beliefs and values within a company obviously depends on both wider cultural processes and on its particular recruitment, socialization, and promotion practices.

Over time, the structure of an organization, its control system, and the beliefs and values of its members often change in response to changes in the external environment. The degree to which such internal features have an independent explanatory role depends on how rapidly they alter in response to such external changes and on how much discretion the organization has once such readjustments have taken place. In an imperfectly coercive environment, the internal features of an organization will be partially self-determining.[3] The current structure of an organization, its incentive system, and the beliefs and values of its personnel will all reflect its responses to past problems. Hence, an organization's immediate response to current problems, as well as its subsequent reactions if those initial efforts should prove unsuccessful, will tend to reflect its past history and development. In this sense the model is evolutionary as well as institutional although, unlike biological evolution which occurs via arbitrary mutation and natural selection, the evolution of an organization is a process of conscious, incremental self-transformation.

Two major qualifications to this characterization are in order. First, the idiosyncratic character or beliefs of particular individuals within an organization may be causally important. Such factors represent a potentially important source of unexplained (i.e., residual) variation within this framework. Second, the world outside of an organization is not completely exogenous. Instead, organizations often do act to alter what might be seen as external limits and pressures (e.g., by lobbying for new legislation or developing new technology). These additional complexities should be kept clearly in mind in the analysis of specific decisions and cases.

II. Study Design

The framework just presented suggests (as will become clear below) that the internal features of an organization will have the most impact on decisions that are uncertain, complex, and long term, and when the industry involved is imperfectly competitive. To facilitate this admittedly exploratory research, such a set of choices was selected for study: the environmental and related capital investment decisions of three public and three private electric utilities. A set of companies was chosen which exhibit much variety in their internal structures, incentive systems, and in the external situations they confront. These were: the Tennessee Valley Authority (*TVA*), the Ontario Hydroelectric Commission, the Los Angeles Department of Water and Power (*LADWP*), Pacific Gas and Electric (*PG & E*), the Southern Company, and Boston Edison.

This sample includes one public and one private company in each of three regions, which crudely controls for some variations in input prices and political context. A wide range of behavior is also represented: some of these companies have done more than formally required, while others have refused to abide by environmental regulations, sought exemptions to them, or worked strenuously for their relaxation. Furthermore, most have exhibited notably uneven performance, taking a lead nationally in some technologies or problem areas, while doing much less elsewhere.

The primary data base consists of twenty to forty interviews per company, of an hour or more, ranging from chief executives to nonsupervisory technical personnel in various functional divisions. Published and unpublished materials were reviewed and interviews with relevant outsiders were also conducted.[4] The interviews explored both the specific events that lead to certain decisions and the structure and functioning of the organization and the nature of its members more generally.

---

[3] By "imperfectly coercive" I mean that knowing simply the current external situation will not allow one to exactly predict the behavior of the organization. Instead, as in all "satisficing" models, observed outcomes depend on the history of the system.

Given the lack of published materials with the necessary detail, there was no other methodology available for establishing what exactly has occurred in each company. Interviews also provide direct information on the values and perceived incentives of various organization members, important data within our analytical framework. Intensive case studies were carried out in the hope that this would make it possible to discover to what extent particular individual actions were a response to external or internal aspects of the situation. This requires an understanding of whether there were alternative, and also functional, strategies which could have been, but were not, adopted by the organization and why events occurred as they did. Furthermore, detailed knowledge of at least a few cases makes one aware of the limitations of alternative simplified models and hypotheses and allows one to choose among them in an informed manner.

The interviews were off the record and subject to prior clearance before attribution. Obviously such data must be used skeptically, and cross-checking among various internal and external sources is essential. Yet, while some faulty memories and apparently conscious deceptions were encountered, many of those interviewed were both outspoken and critical in discussing their company's decision making. Thus it was possible to construct an overall picture of how each organization has functioned and to relate this synthesis to a detailed account of a number of specific decisions in each company. Space constraints dictate that case studies cannot be presented in detail. Instead the following section reviews the general propositions which the study suggests and briefly illustrates these from the case material.

III. Proposed Hypotheses and Findings

Since the more general results of this study were developed through the interaction of both inductive and deductive methods, their current status is that of proposed hypotheses which are nonetheless consistent with both the analytical framework and the available empirical evidence. For each of the five sets of generalizations to be discussed, we will proceed from the conceptual to the empirical, recognizing that verbal analytical arguments, like all theorizing, involve essentially a tautological restatement of the assumptions in a manner which serves to clarify their otherwise unperceived implications.

In order to construct certain hypotheses, it is useful to distinguish among various kinds of control systems. I will call the control system "weak" when, for different individual actions that lead to different organization outcomes, an individual confronts similar multivariate probability distributions with respect to firm-provided rewards and sanctions. In such cases, the individual will typically have little to gain or lose financially by various actions. Hence he must resort to other personal, professional, or organizational values in order to resolve his decision problem. The difficulty of providing a strong control system leads some organizations to rely instead on inculcating an ideology. Thus we can distinguish three types of situations.

---

[4] See Roberts (1975) for a full list of interviews and an extensive bibliography. That manuscript should be considered the source for all specific empirical statements which follow.

(1) The stronger is the control system in an organization, the more impact the values and beliefs of top management will have on the organization's choices, if top management so chooses.

(2) The weaker is the control system, and the more the organization relies instead on developing an ideology for control purposes, the more difficult it will be for top management to alter the organization's choices. In such cases, change occurs only slowly or not at all, even in the face of substantial external pressure. The gap between top management's goals and actual outcomes will depend in part on the content and flexibility of the corporate ideology and on the relationship of these to the particular aims being sought.

(3) When the control system is weak, and the organization does not possess a well-developed ideology, authority will often be delegated with little supervision since middle managers have no incentive to do otherwise. As a result, the values implicit in a decision will vary, depending upon the particular individuals who make the choice in question. Such situations are only functional when the organization is relatively free of external pressures.

To illustrate these hypotheses it is useful to begin with *TVA*, an organization with a very strong ideology and a control system that places only limited power in the hands of top management. Except for the one or two levels just below top management, promotion and compensation are decided largely in each of the seventeen divisions and offices—all of which report directly to the General Manager. With only a small staff, he and the three-man Board of Directors do not find it easy to keep informed of *TVA*'s multifarious activities, still less to supervise them closely. Policy is typically set by negotiation among the various divisions and offices. For complex historical and bureaucratic reasons, the largest and most influential of these, the Office of Power, has been committed to the notion that *TVA* should minimize power costs; and other divisions have had every reason to develop complementary, not competitive, strategies.

This internal situation became quite important when the Board of Directors voted in 1959 to achieve "clear stacks" at the Kingston power plant by installing high-efficiency electrostatic precipitators to remove fly ash. A strong ideology that had different policy implications could not be overcome by a control system that gave top management little leverage. In an effort to minimize costs, underdesign, poor construction, and inadequate maintenance all occurred. Today the precipitators work very poorly, and with state prodding, a major retrofit is being undertaken.

In contrast *PG & E* has a strong control system. Top management has much discretion in promotions and the like and participates actively in such decisions quite far down into the organization. As a result, the enthusiasm of top management for building a nuclear power plant on the coast north of San Francisco led to not one but two such attempts, despite reservations on the part of some technical personnel. The first site was rejected on geologic grounds by the Atomic Energy Commission after a multimillion dollar investment by the company. Yet only a few years later and not 100 miles away, the company made a second, equally expensive and equally unsuccessful, effort. Subordinates who were trying to please their superiors were not eager to question the wisdom of the latter's chosen course.

In contrast, since most promotion in the Los Angeles Department of Water and Power depends on Civil Service examinations, it has a relatively weak control system (and, in recent years, a weak ideology). As the proposed hypotheses suggest, the choices of this organization are not obviously consistent. Long a leader in beautifying and landscaping substations, it nonetheless has often faced vigorous community opposition over transmission line rights-of-way. In part this is because the architects who do station design see "client" concerns as more legitimate than the electrical engineers who are responsible for power-line routing. And each has some freedom to make choices in what it believes to be a professionally correct way because of the weak control system.

Our second set of hypotheses concerns the implications of this framework for cost minimization and profit maximization. Here a serious analytical difficulty arises. What standard of comparison should we use? One can argue that intendedly but imperfectly rational decision makers, by definition, never made mistakes *ex ante*. Hence, to consider a decision in error we need either more knowledge, better analytical capacity, or different objectives than the actors involved. In the following hypotheses, therefore, we employ an *ex post* standard, realizing that the test may not be "fair" in some sense, even though it is the accepted perspective for evaluating economic performance.

(4) Information and decision costs, organizational imperfections, and bad luck mean that organizations will not optimally achieve *ex post* minimum costs, maximum profits, or any other goal subscribed to by top management.[5]

(5) A weak control system, without a counterbalancing ideology, will lead to effort-reducing capital investments, overmanning, and a failure to minimize costs in routine operations. A corollary to this hypothesis and hypothesis (2) is that organizations subject to strong external pressures (e.g., survival threats) will not exhibit this structure-behavior problem.

With regard to cost minimization, most of the companies studied have had significant engineering problems. For example, one has a large coal-fired plant whose boilers are too small, and the unit cannot operate at full load for more than short periods. Another installed an innovative cooling system that has not worked properly, and that unit too cannot function at full power for extended periods. And the list could be extended easily much further. In all of these cases, cost minimization was an avowed and accepted internal goal, and extensive engineering studies were made. But because the problems were difficult, *ex post* minimization did not occur.

As to cost consciousness generally, some utilities like *PG&E* and *TVA* are very cost conscious. In the first case, the unique constitutional situation in California makes that company fearful of local referenda on expanded municipalization of its distribution network, an external constraint which has deeply influenced corporate strategy and structure. *TVA*, in contrast, has had only moderate external cost constraints,[6] but the internal mechanisms noted previously have led to similar results. *LADWP*, on the other hand, was, in the opinion of several of its own senior engineers, more "service" than cost oriented—at least until quite recently. With steadily declining costs and rates set by a City Council favorable to the department, the self-interest of organization members in large staffs, and light work loads and professional norms sanctioning technocratic excellence played a significant role in the allocation of corporate resources.

The third set of hypotheses concerns

---

[5] This also means that effectively regulated companies will not perfectly maximize net revenues by precisely adjusting their capital stock above cost-minimizing levels (the so-called Averch-Johnson effect). Since these companies all enjoyed substantial regulatory lag, however, it is not clear how much one should expect this phenomenon.

[6] *TVA* has no state rate regulation. Indeed, it acted aggressively through most of its history to force municipalities and cooperatives that resold its power to lower their rates.

what determines the strategy of an organization and the role of various groups of individuals with similar perspectives in that process. The prevalence and cohesiveness of such groups in a company depend upon how the process of recruitment and socialization and the operations of the control system serve to reinforce or break down common perspectives and incentives.

(6) The assumptions implicit in professional training, plus more or less conscious self-interest, mean that groups typically view the organization's problems in ways that place special importance on their own responsibilities and skills.

(7) Where promotion is vertical and seniority important, an individual's prospects for advancement depend heavily on the growth of the unit to which he is attached. In such circumstances, bureaucratic units will tend to become cohesive groups. In contrast, where horizontal and diagonal mobility are more frequent, broader information and different incentives decrease the cohesion of bureaucratic units.

(8) The influence of various groups will be enhanced by: the number of group members; the amount of work assigned exclusively to them; the position and personal stature of the group's senior executive; the number of group members in top management or in other bureaucratic units; and the extensiveness and coherence of prior professional training and distinct work experiences among group members.

(9) The balance of group perspectives within an organization will have more influence on its choices when the available policy options are more numerous, uncertain, apparently similar, and difficult to evaluate. In such instances (e.g., choice of a new technology), strategies that lack group advocates will seldom be adopted.

In fact, in the cases studied, groups in the sense used here were a major factor in organizational decision making. At *TVA*, where there was least horizontal mobility, bureaucratic units most clearly played such a role. In certain other companies this was less marked, in part because several had intentionally tried to rotate personnel and reorganize bureaucratic divisions in order to blur traditional distinctions and rivalries.

Group attitudes were often self-serving. Operators, who must fix plants when they fail, argue for reliability and redundancy in design. Public relations people, lawyers, financial specialists, and marketing personnel all insist on the centrality of their role and the importance of keeping "their" considerations in mind in corporate policymaking. Such stereotypes are widely accepted in the industry, as the following quotations illustrate. These come from senior engineers, one in a public and one in a private company: "He's a P.R. guy; he would give the company away if no one was looking." "When I first came here (to operations) I thought like a design engineer. Now my friends in engineering say I always sound like an operator."

Our data also confirm, in an illustrative manner, the hypotheses advanced above about the causes of a group's influence. For example, consider how the Los Angeles Department of Water and Power wound up constructing the Scattergood Unit Number 3, which the local Air Pollution Control district will not allow to be operated at over 60 percent of capacity. During and after World War II, the department underwent a conscious transformation as the Mayor brought in a new administration in an effort to remove the *LADWP* from its previous extensive involvement in local politics. One result of these changes was to eliminate many previous positions and limit the department to a small public relations group which reported directly to a single General Manager, who supervised both the water and the power systems. At the same time, the department had no legal staff of its own. Instead it used a branch of the City Attorney's office, whose members were not directly under the Chief Engineer's supervision. Hence, the management of the power system simply did not have much input from or access to specialists expert in interacting with the public or in handling regulatory processes.

Thus, when the construction permit for the plant in question was not forthcoming from the Air Pollution Control District, the department's management apparently assumed that their view that the plant was necessary simply would prevail in the end. No one in the department argued that a sophisticated analysis of the political pressures on, and the likely reaction of, the regulatory authority suggested the need for a different strategy—at least not until after construction was halted by legal action. Instead, a mechanical engineer and a busy top executive handled the matter, with very undesirable results from the department's viewpoint. Such events would be very unlikely, in contrast, in an organization like *PG & E*, a company very conscious of public opinion and political constraints, with several lawyers in key general management positions and very large in-house public affairs and legal departments deeply involved in most significant decisions.

Particular groups with particular interests have also been responsible for most of these organizations' ventures into new technologies. At the Southern Company, the Research Department entrepreneured an extensive program of research on solvent-refined coal. At *TVA*, the Air Quality Branch has taken the lead in developing operational control methods for meeting ambient air quality standards by varying power plant operations. A group of mechanical engineers at Boston Edison took the initiative and did the work that made possible that company's extensive involvement in stack gas-scrubbing experiments. And the transmission engineers who lead the *LADWP* were crucial to that organization's decision to construct a pioneering 800 kilovolt D.C. intertie to the Bonneville Power Authority. In all these cases, the companies have been leaders nationally in these particular areas, while not being notably adventurous in other respects.

The fourth set of hypotheses concerns the influence of the political system, which ultimately has great power over both the structure and the external situation of most organizations in the society. Note, however, that in practice the legal limits it can impose are not inviolable constraints. Rather they confront the firm with a set of multivariate probability distributions over various costs and consequences (fines, delay, etc.) contingent on its own actions.

(10) Because the categories "public" and "private" include organizations that exhibit a wide (and overlapping) set of internal features and external circumstances, that distinction contains little predictive information about behavioral differences.

(11) To the extent that legal arrangements raise the transaction costs that political actors face in attempting to control an organization, the organization will confront relatively less restrictive external limits.

> If the organization's budget requires routine political approval, the costs of political control tend to be lower and the extent of such control correspondingly higher.
>
> If political control requires the coordinated action of more than one political entity, the costs of such control tend to be higher and its extent correspondingly lower.
>
> If different individuals and political actors face different costs and benefits from altering the policy of an organization, those who face the lower costs and stand to enjoy the higher benefits will be

> more favored by organization's decisions. Such variations in costs and benefits will typically develop when the geographic scope of an organization's activities is smaller or larger than that of the political entity to which it is nominally responsible.

On the public-private distinction, our studies show that some public and some private companies are cost conscious and others are less so. Some in each category have made great efforts in the environmental area while others have done relatively little. The critical role of government control over access to capital is also apparent in the cases. An organization like Ontario Hydro, whose budget is routinely reviewed and approved by the Provincial Cabinet, is far more vulnerable to (and hence responsive to) political pressures than *TVA* or *LADWP*, which are financed from retained earnings and revenue bonds and whose budgets do not require anyone else's approval.

The cases also suggest that when a company is smaller than the scope of the relevant political system, as *TVA* is versus the national government, it becomes much less likely that the political entities in question will mobilize to control the organization's policy. In such instances, after all, that policy is of interest to only a minority of the government's citizens. On the other hand, *LADWP* illustrates the hypothesized tendency for an organization to treat those who face high costs in influencing it differently than those who face low costs. With the urging of the County Air Pollution Control District, the department took the view in the late 1960's that the environmental problems caused by generating power for Los Angeles could and should be solved by constructing new facilities in other areas—whose citizens voted in neither city nor county elections.[7] This part of the argument is especially significant in light of the suggestion often advanced in recent years for the creation of special regional agencies to deal with various environmental purposes. Unless these are carefully designed, they would appear to be very costly to control in terms of political resources, and hence less likely to be so controlled (cf. the New York Port Authority).

Finally, we can offer some hypotheses about the evolutionary process by which organizations respond to changing external circumstances. To some extent, such changes reflect whatever capacity top management possesses to purposefully alter the structure, incentives, and personnel of the organization, although the results of such actions are not always fully anticipated. Yet, the goals and strategies that shape such management actions are not themselves entirely exogenous; top managers, after all, are typically chosen by their predecessors or by others within the organization.

(12) Since individuals generally prefer to be identified with socially acceptable organizations, changing social attitudes will tend to result in some changes in an organization's behavior, provided that other pressures or beliefs do not have different implications.

> Because newer and younger members often have more "modern" views than those they replace, more rapid personnel turnover facilitates changes in an organization's behavior in currently socially sanctioned directions.
>
> For top management to alter a widely held strategy in an organization with a strong ideology, it may be necessary to advance new individuals, especially outsiders, to key positions.

(13) Changes in an organization's struc-

---

[7] The department has been a major participant in coal-fired power plants in Arizona and Nevada and was a central advocate of the unsuccessful Bridge Canyon proposal, which involved a dam on the Colorado River that would have backed water up into Grand Canyon.

ture undertaken to facilitate the accomplishment of chosen policies not infrequently lead to unanticipated changes in those policies.

(14) When an organization's chosen strategy appears to be unsatisfactory, the initial response often is to make an effort to change one of the binding external constraints.

The detailed studies have developed much interesting material on these last issues. In almost every company some members, especially younger ones, were willing to criticize their own superiors for not doing more about air and water pollution. Similarly, time and again, a change in management has been associated with a change in policy. In Los Angeles, for example, several City Hall observers commented on the more flexible and publicly sensitive approach of the new management of the Department of Water and Power—an observation made as well by a number of those inside the organization.

The impact of changing social attitudes is very evident. Most older executives assert that their views, or the organization's policy, or both, have changed in recent years. The typical position is that the only real issue is how much to spend on environmental protection to correctly balance the costs against benefits. Ten years ago these men, and by their own accounts their predecessors, would have taken a noticeably different position.

Changes in policy obviously also arise because chief executives have consciously altered the structure and personnel of their organization in order to alter its behavior. But their ability to do so is often not unlimited. In *TVA*, for example, most individuals at all supervisory levels share a commitment to producing power at the lowest possible costs as the dominant policy goal. Perhaps in response, in order to obtain more policy flexibility and personal control, the current General Manager has made at least three senior appointments in recent years from outside the Authority.

There are also cases where changes undertaken for one reason have had unanticipated effects. One company created a Research and Environment Division that soon moved energetically to expand the corporation's environmental research and development program. And, if not always successful, there is reason to believe that it has succeeded more than some foresaw when it was first established.[8]

The cases also show organizations responding to "problems" by trying to change nominally external pressures and limits. For example, both the Southern Company and *LADWP* pleaded poverty and halted work on major projects during rate disputes. Intentionally or not, in both cases this provoked political efforts in favor of rate increases by the construction unions whose members were thereby unemployed. Just recently *TVA* lobbied a bill through Congress to have the Treasury in effect pay for its pollution control investments (only to have it vetoed). The willingness of organizations to take various risks and to attempt to relax one or another constraint depends in part on the details of corporate policy formation and the balance among group perspectives as discussed previously.

IV. Conclusions

The preceding discussion implies that there may be no simple explanation of the inter- and intra-corporate behavior patterns that we are interested in. *PG&E* has "clear stacks" and *TVA* does not. On examination this difference turns out to be a function of a complicated set of differences in history, fuel prices, external pressures, the strength of internal control mechanisms, and the balance of group perspectives within each organization.

---

[8] In this company, budgetary procedures for research have become significantly more formalized in the last year.

The proposed hypotheses admittedly do not impose highly restrictive limits on the behavior of organizations. Like consumer theory in general, one cannot get detailed results from general assumptions. The argument has assumed little more than that people are intendedly rational, that decision making and information are expensive, and that tastes and beliefs are influenced by experience. To get more specific implications, one needs to postulate more specific conditions. For example, hypotheses (6) and (8) together might be specialized as follows: "In electric utilities, power plant operators value plant reliability. Hence, the forced outage rate of a system's facilities will be inversely related to the seniority and influence of the company's chief operating official and to the percentage of the organization's technical personnel who were operators at the time the plant was designed."[9] That generalization, and others like it, I hope to subject to statistical confirmation in future research efforts.

On the other hand, not all that can be learned about organizations and their functioning can be summarized in a set of formal hypotheses. The design of organizations for policy purposes, like, say, the design of sailing boats, will retain an important component of nonspecifiable craft skill for the foreseeable future (Roberts 1974). That does not mean, of course, that we should not try to systematically write down as much as we can about the orderly features of the relevant phenomena. But I believe that there is a value in being familiar with the details of particular situations, for policy as well as historical purposes, hence, the detailed manuscript which includes the full case studies, which is in preparation.

Finally, I contend that this study has been fruitful enough to show that there is something to be learned from disaggregating economic entities in order to better conceptualize their behavior. No doubt simple profit maximization explains a good deal in some cases. But it explains much less in others. And shouldn't we want to be able to account for such variations? Modern chemists explain the behavior of a substance by reference to its molecular and atomic substructure. Perhaps economists have been a bit too optimistic and, like medieval chemists, have viewed the world in terms of categories that are too few and too aggregated. If the disaggregation and detail of the evolutionary institutional viewpoint can improve our understanding, generate new hypotheses, and reduce the margin of unexplained residual variance, it would seem to be worthy of further attention, especially in those cases like public enterprises, where no "black box" model readily suggests itself.

THE PRINCIPLES COURSE: WHAT SHOULD BE IN IT AND WHERE SHOULD IT BE GOING?

Some Observations on the Learning of Economics

By KENNETH E. BOULDING*

We probably pay too much attention to the teaching of economics and not enough to the learning of it, that is, to those processes of reorganization in the cognitive structure or image which result from being exposed to the body of public knowledge which economists share. All learning processes involve the reconstruction of images. This sometimes involves fairly drastic reorganization change in existing images; sometimes it merely involves addition to the existing structure. Thus, when we learn that Sacramento is the capital of California, this simply adds to our geographical knowledge of the United States without any very fundamental change in the structure. When we learn, however, that the shortest way from California to Iran is over the North Pole, if we have previously structured our world on Mercator's Projection, this is quite a shock and will create a considerable reorganization of our geographical image. The learning process, therefore, depends a great deal on where people start from, that is, what images of the system they have in their minds at the beginning of the process; and it depends also on the creation of certain shocks or inconsistencies, what Leon Festinger has called "cognitive dissonances," which force a reorganization of the structure of these initial images.

In discussing the teaching of economics, we have usually been singularly insensitive to the problem of what images of the economic system people start with. If we don't know what it is we are modifying, we may not be successful in modifying it. In a sense the object of formal education is to move images in the minds of the students from private and idiosyncratic images toward publicly held images. This is not to say that the public image is always right. Indeed, change in the public image always arises because some private, idiosyncratic image fails to correspond to it, although it corresponds more to the truth. Nevertheless, for most purposes we assume that the teacher's image is "right" and that the student's initial image is "wrong" and that the business of education is to change the image in the mind of the student in the direction of the image in the mind of the teacher.

If we look at the learning process in this way, it might occasion a certain change in our methods of teaching. The traditional method is to create a large flood of information input into the student's ear, and perhaps into his eye, in the hope that this input will create a change in the student's image in the direction of that held by the teacher. Most of the feedback to the teacher, however, comes from his own internal perceptions as to whether the information stream which he is emitting is consonant with the image which he holds.

---

* University of Colorado.

He gets very little feedback from the student and is often quite unaware that the information stream which he is transmitting may have a completely different effect on the image of the student from what it is supposed to have. It may, of course, go in one ear and out the other; it may simply be filtered out; or it may be filtered in such a way as to create transformations in the student's image which do not correspond to the intentions of the teacher.

Once we concentrate on the learning process rather than on the teaching process, we tend to start off with creating in the mind of the teacher an image of what is the initial state of the mind of the student. The process should begin, therefore, with some sort of inventory or examination which will improve both the student's and the teacher's perception of the student's present image. This could include a vocabulary test to investigate the student's image of the meaning of the major terms in the field. It should also include a test of quantitative estimates to get at a student's image of the quantitative proportions of the economy. I find even with graduate students, for instance, that they grossly overestimate the proportion of national income going into profits. Another useful inventory would probe what the student sees as the major problem of the subject, that is, what questions does he want this course of study to enable him to answer. A very good exercise indeed might be to make the student at the outset write a set of examination questions so that the student is in effect setting an examination for the teacher.

Once these initial inventories are in, the student should be faced by a cognitive dissonance, that is, by whatever contrast there may be between his own image of the world as revealed in the inventory and the teacher's image, which one hopes is part of the public image. A course of directed reading might follow, designed to enrich the student's vocabulary, acquaint him with concepts, and generally modify his image in the direction of that of the teacher or of the profession. In the natural sciences, it is possible to give the student laboratory experience of the "real world," although this is often pretty contrived, and what the student is often really doing in the laboratory is trying to find the answer that will please the teacher, just as he is in class. In the social sciences, laboratory experience is much more difficult. Nevertheless, the presentation of historical and factual materials and then setting the student to the task of interpreting these materials according to his own images of the world may have all the impacts of the laboratory. Statistical time charts are of particular value in this connection; so are maps, distributions, and expressions of quantitative data.

The hardest part is, of course, the image of relationships or models. Here the student may have extremely vague ideas before he begins to study. Hence, what is happening is not so much the reorganization of existing inaccurate images, but the creation of new kinds of images altogether. How this is done is a bit of a mystery. The response of a student depends a great deal on his "readiness," but this is very hard to discover. I have had students who have just had an experience of enlightenment come to me and say, "Why didn't you tell me that six months ago?" to which I usually reply, "I did, but you weren't ready for it." It may be that the only answer to the readiness problem is a good deal of redundancy in the teaching process. It is not so much that what I tell you three times is true, as what I tell you three times may be believed on the third try. It may well be, therefore, that the presentation of material can be too orderly in a field which is a "round globe of knowledge," like economics, where the understanding of one part depends very much

Some Comments on the Principles Course

By JOHN G. GURLEY*

Quite aside from what *should* be taught in our principles course, what is in fact taught is a system of economic ideas which come from social practice—from our efforts over time to develop our productive forces and from the class struggles that have changed our social relations. These struggles with nature and with one another govern pretty much what we think. This suggests that one way to teach elementary economics is to relate the development of economic thought to the development of society's economic base. In this way, students would be given a feeling for the relation of theory to practice, some sense of history, and the knowledge that systems of ideas do not drop out of the sky. This is what Joan Robinson and John Eatwell have done in their recent text, *An Introduction to Modern Economics.* E. L. Hunt and H. Sherman in their text, *Economics*, also follow this procedure. Such an approach is necessarily radical, for it cannot help but expose the extent to which economic theories are rationalizations of advantages held by ruling classes.

Since our own social practice takes place within the capitalist mode of production, in which the dominant social relations are bourgeois and the leading class is the capitalist one, our principles course mainly reflects and supports this type of social arrangement, so that the valuable lesson taught by the above authors is missing. Instead, capitalism is presented as a generally harmonious, equilibrating, efficient, and equitable system—at least potentially so—as a system with problems which are largely solvable with intelligence and good will and, if history is mentioned at all, as a system that represents the zenith of an historical process. Profits and other property income are justified and raised to the same moral plane as wages; and the real, underlying exploitative relations of capitalist society are hidden under a layer of exchange equalities and contract freedoms.

However, in a capitalist society, when the working class has come of age and its own ideologists have gained sufficient understanding of how the system works, then another complex of economic ideas appears, a complex which reflects the position and interests of the working class, reveals the exploitative relations and contradictions of capitalism, and shows its salient features and its transitory nature.

Therefore, in a class society such as ours, there will necessarily be two major—and no doubt several minor—ideological reflections of that class structure. This is why, although the dominant economic theory is bourgeois, there also exist principles texts expounding radical, institutional, romantic, and other approaches. At this level of discussion, the question of what "should" be taught is primarily a matter of which class to support and secondarily a matter of form.

For a long time, up to World War I, the capitalist mode of production destroyed all barriers in its headlong drive for hegemony around the world. This overwhelming material force of commodities and military weapons was reflected in the intellectual dominance of bourgeois thought in economics and other disciplines. In the past half century, however, at first slowly and lately more rapidly, international capitalism has been weakened. Some of the forces responsible for this have been the two world wars between the newly rising and the already established capitalist powers; the expansion of communism, which has now swept across a third of the globe; the rise of national liberation and ultranationalist movements throughout much of the underdeveloped world; the growing control exerted by third world countries over the raw materials and natural resources so badly needed by the capitalist nations; and the dwindling supplies of cheap labor available to the leading capitalist countries, which have resulted in the strengthening of labor relative to capital. In the past few decades, *U.S.* capitalism in particular has also been hit by intense competition from other capitalist powers. These adverse winds have tended to erode profit opportunities of *U.S.* capitalist enterprises, which they, supported by the State, have attempted to restore by exerting additional pressures on the working classes.

---

* Professor of economics, Stanford University.

Such dramatic changes in fortune in the material world opened the way for increasingly successful intellectual forays against the growing disarray of bourgeois thought. In economics, this has taken the form of a renewed challenge by Marxism, radicalism, and alternative approaches to conventional, neoclassical analysis. Bourgeois economists have been busily engaged in fending off these challenges and in trying to patch up the conventional analysis faster than new disasters and puzzles appear. Accordingly, we now find in our principles texts, not only signs of apprehension about existing theory, but also new sections on tradeoffs between unemployment and inflation and between growth and environmental decay, the woes of the *U.S.* dollar, the impact of multinational corporations, and the continuing failures of capitalism to alleviate poverty and misery in much of the world, including in our own backyards. Even though the authors put the best face they can on these problems, it is quite understandable that, in their search for further guidance or to discredit obvious alternatives, they should also add chapters on Marxism, comparative economic systems, and planning and controls. It is likewise no surprise to find some of them giving more attention to the history of economic thought as their own doubts increase about the continuing viability of conventional doctrine. When one suspects the child, one investigates its parents.

Thus, it has not been a matter of freely searching for what seems to be ideally right to put in our principles texts, but rather one of trying to understand and adjust to the powerful historical forces that so heavily bear down on us. Since these forces have favored economists who attack capitalism, conventional economists have been put more and more on the defensive, and the principles texts clearly show this. In the end, the Vietcong will probably have more to do with changing our principles course than all the roundtable debates such as this one from now to kingdom come.

While conventional principles texts have certainly changed in response to real movements in the world, the changes have not been uniformly for the better. Some authors, on the defensive, have simply reiterated, only in louder and louder tones, that capitalism's mounting problems are solvable within the system itself, by making the system work better. Others treat such topics as Marxism, socialism, and capitalism (as a system) most inadequately. Thus, we find in the principles texts that capitalism is often defined so as to hide its class nature. One author of a popular text even believes that the word "capitalism" is too emotionally charged to be safely used. He and other authors often put the word in quotation marks, as though it is being gingerly and warily held up by its corners for fear of contaminating its holders. When it comes to Marxian economics, conventional authors make one mistake after another and appear to have the weirdest notions of what the subject is all about. Some make a real mess of the whole thing. Even Paul Samuelson, who has by far the best discussion of Karl Marx among the textbook authors I have read, presents Marx incorrectly at times, superficially at other times, sometimes shabbily, and often with trickery. Few authors seem aware that there have been other Marxists than Marx—that, over the past century, a large and rich Marxian literature has been fashioned which is valuable for understanding modern-day Marxian economics. Marxism is not only generally emasculated by these authors, but it is also treated in such isolation from the rest of the material that it appears to be some new, exotic "field" in economics, rather than what it is, a mode of thought that challenges every single aspect of conventional economic theory—the ideological counterpart of the working classes' challenge to every single aspect of the monopoly of private property ownership.

I do not think, therefore, that Marxian economics can be properly presented in a bourgeois textbook. It should and will make its appearance increasingly in radical textbooks and in books of readings which will compete with the conventional offerings. The outcome of this intellectual clash will be determined by the outcome of the many struggles between the capitalist and working classes, which are now being waged on every part of the globe, for the ownership and control of the world's means of production and natural resources. Marxists believe, to put it bluntly, that marginal productivity theory will disappear only with the bourgeoisie.

Finally, with regard to what I have called the secondary consideration (but, still, one of great importance)—i.e., the form in which any set of economic ideas is taught to beginning economics students—the ideal way would be some combination of theory and practice, in which the students, while learning theory, directly investigate problems in the real world to which their theory may be applied. But since existing arrangements hardly encourage this, the closest and next best method is to teach only a small amount of theory to permit sufficient time for students to apply it to case studies as they go along. In this I agree with what Rendigs Fels said last year, when he advocated less stress on theory that is important mainly to the professional economists (and which, in any case, I would add, is mostly empty), more stress on a few basic macro and micro tools of analysis, and more emphasis on the use of these tools to solve actual problems. Students now have so much theory thrown at them—especially right now when theories are proliferating to cover up failures of previous theories—and so little time to use the tools that they very soon forget just about everything they have heard or read. G. L. Bach, Richard Attiyeh, Keith Lumsden, Fels, and others surely are on the right track in designing interesting and challenging case studies for beginning economics students to work on. This is the direction the principles course should be going.

New Approaches to Teaching the Principles Course

By W. LEE HANSEN*

Had any of us been asked to serve on a panel like this ten years ago, I assume we would have been perplexed about what to say, and this would not have reflected the fact that all of us were then ten years younger. At that time there seemed to be little dispute about the content and direction of the principles course. A substantial consensus existed within the profession as to what economics was all about. This was reflected in the second, third, or fourth editions of those superbly produced, massive forty-five-chapter principles texts, which, replete with color diagrams and accompanying readings and workbooks, covered most everything economics had to offer. This made the role of the instructor an easy one, for after selecting a text, the book did the instructing. Everyone seemed satisfied. Students weren't complaining. And faculty members had ample time to turn to other things, among them their research, the building of graduate programs, and faculty recruitment.

But today I expect those of us on the panel have more thoughts racing through our heads than any of us can present to you. What does seem clear, however, is that the principles course is in a state of transition. There is vastly greater variety in the nature and content of principles courses, the teaching materials employed, and the teaching approaches instructors are developing. These changes reflect a response to a variety of largely unanticipated developments over the past decade. The emergence of new issues and problems—the Vietnam war, poverty, environment, and the like, coupled with the challenge posed by radical economics—has called for new, or at least different, approaches than those customarily used in principles courses. Closely related is the shift in research interests of faculty who perceived a growing gap between what was traditionally taught and the things of most interest and concern to them. At the same time student pressures for better teaching, greater "relevance," and other academic reforms sensitized faculty to the need for rethinking their teaching of the principles course, both with respect to what they were teaching and how they were teaching it. In addition, the small but rapidly growing body of research on economics instruction indicated that the effectiveness of the standard principles course left much to be desired. Then during the past couple of years intensive competition for student enrollments (because of their implications for faculty staffing) has emphasized the need to make economics courses more attractive to our students. And most recently, the confusion both inside and outside the profession about how to cope with current policy issues, particularly inflation and unemployment, indicates that much remains to be done to develop the required degree of economic literacy.

What kinds of responses do we observe to these diverse forces? First, a small but growing number of faculty members are revamping their principles courses. They are shifting away from the long-standing practice of trying to survey the entire field of economics. Instead, the focus has been on narrowing the scope of the course to something far more manageable, in the hope that longer lasting learning will be the result. Concern over the ever expanding scope of the principles course was voiced as long ago as 1950 in the American Economic Association's report on *The Teaching of Undergraduate Economics.*

---

* University of Wisconsin-Madison.

Second, rather than preparing students for upper-division courses most of them never go on to take anyway, a more applied emphasis is emerging. It appears to be motivated by the question: How can economics be taught so that students by the end of the course can understand the kinds of economic problems they will be reading about and involved in throughout their adult lives? We see this changed emphasis reflected in the breakup of the principles books into micro and macro sections, in the development of a wide array of new smaller "problems" texts, and in the welcome proliferation of paperbacks and reprints on special topics. Taken together they permit the creation of one's own textbook through a skillful combination of available materials, supplemented by articles instructors choose to reproduce out of daily newspapers.

We also find an impressive collection of completely new paperback texts which capture the essence of various new experimental and innovative principles courses, many of which have been supported by the Joint Council on Economic Education. Let me list a few of these courses. We have the "case approach" developed by Rendigs Fels and others at Vanderbilt, the "current issues approach" reflected in the Oklahoma State course created by Richard Leftwich and Ansel Sharp, the "core concepts, problems approach" followed by Phillip Saunders at Indiana and also by our chairperson, G. L. Bach at Stanford, and the "social systems approach" being developed by fellow panelist Kenneth Boulding at Colorado. In addition, similar developments are taking place elsewhere; included is the emergence of radical economics courses at the principles level. We also see a few cases in which individuals are putting their own specialized stamp on a course, as exemplified by John Kuhlman's course at Missouri. What I find most heartening about all of this is the heavy involvement of individual faculty members across the country in developing new approaches that most closely fit their conception of what economics is all about.

Another noteworthy change is the experimentation going on with alternative teaching techniques. Elisabeth Allison at Harvard has developed a Keller-type, self-paced approach; Donald Paden at Illinois is working with a *PLATO*, computer-based teaching system; Allen Kelley at Duke operates an ambitious, diversified instructional program centered around his *TIPS* system; and so on. Obviously, the costs of course development, both to individual faculty and their supporting institutions, are substantial, but only by making such investments can new, more effective instructional systems be identified and developed.

Closely related is the emphasis more and more economists now give to the evaluation of their instructional efforts. Increasingly, we find them applying the research tools of their trade to measuring how the various elements of instruction and student behaviors and abilities interact to produce greater (we hope) student learning and interest in economics. The results of this work are finding their way into print, in the flourishing *Journal of Economic Education.* The establishment of this journal, by the way, represents a triumph in economic thinking, for it has cleverly helped convert teaching and research into complementary rather than competing activities that vie for faculty time and effort.

Last are the accelerating efforts to give more attention to pedagogy in the training of graduate students who anticipate teaching careers. The economics profession has long recognized its failure to do an adequate training job; this was made abundantly clear in the Association's now almost-forgotten 1953 report on *Graduate Education in Economics*. In an effort to prepare aspiring faculty members for their most important professional activity, that of teaching, the Joint Council, in collaboration with a number of major Ph.D.-granting departments, has inaugurated a teacher training program. This five-year project cannot help but heighten the awareness and interest of younger economists in the all-important work of teaching, especially the teaching of the principles course.

The length and scope of this list of recent developments strike me as impressive given the relatively low weight we assign to the teaching of freshmen and sophomores as compared to economics majors and graduate students. But impressive as this list may be, we should not delude ourselves that shifts in content and emphasis, innovative teaching materials, and new pedagogical techniques will themselves revolutionize economics instruction. Rather, whatever success is achieved in producing improved teaching and learning will be the result of greater attention by faculty members to such things as the development of course objectives, better organization and preparation, and greater demonstrated interest in what they are trying to teach their students.

Some of you may view these efforts as representing patchwork when major change is needed. Perhaps this is true. On the other hand, there is no best way to teach economics, however we define it. And there is no single definition of economics that will satisfy all of us. This argues for diversity, as instructors seek to find and develop approaches and techniques that add to their own intellectual excitement and give them a greater sense of craftsmanship. Of course, this assumes that instructors will be challenging their students to learn and in the process will be preparing them to understand the economic issues and problems they will encounter in their adult lives. It also argues for greater attention to disseminating information about new developments in the teaching of economics so that we can all learn more about how other people approach their teaching.

We should also remember that the vast bulk of our principles students will never take another economics course; indeed, many of them now enroll only because they are required to do so. Thus, the task is one of, and I don't like this phrase but can find no other, "turning people on" to economics, not in the sole hope of gaining more majors but rather of imparting to those students who do take economics an understanding that can serve them effectively long after many of the specifics they learned have been forgotten.

This poses a real challenge that each individual and institution will have to meet in its own way. One approach we have tried at Wisconsin in our one-semester principles course (we also have a two-semester sequence) is to adopt a modular format. A number of different faculty participate in the teaching of this single course, with its three lecture sections enrolling a total of over a thousand students. The course begins with a common core of four weeks of applied micro taught by one faculty member, followed by three weeks of macro taught by another faculty member. After that students can choose from a variety of three-week topical modules, taught by still other faculty. The idea of the topical modules is to apply the core material to topics of widespread interest and concern. Thus, we have modules on environmental economics, the role of

AMERICAN ECONOMIC ASSOCIATION

PROCEEDINGS
OF THE
EIGHTY-SEVENTH
ANNUAL
MEETING

SAN FRANCISCO, CALIFORNIA
DECEMBER 28-30, 1974

MINUTES OF THE ANNUAL MEETING
SAN FRANCISCO, CALIFORNIA
DECEMBER 29, 1974

The Eighty-seventh Annual Meeting of the American Economic Association was called to order by President Walter W. Heller at 4:05 p.m., December 29, 1974, in the San Francisco Hilton Hotel.

It was VOTED to approve the minutes of the meeting of December 29, 1973, as published in the *American Economic Review*.

The Secretary (Rendigs Fels) presented the report of the Committee on Elections and the certification of the new officers for 1975 as follows:

In accordance with the bylaws on election procedure, I hereby certify the results of the recent balloting and present the results of the Nominating Committee, the Electoral College, and the Committee on Elections.

The Nominating Committee, consisting of James Tobin, Chairperson, Allen C. Kelley, George L. Perry, Roy Radner, Christopher A. Sims, Alice Vandermeulen, and Charles Z. Wilson, submitted the nominations listed below for Vice-President and member of the Executive Committee. The Electoral College, consisting of the Nominating Committee and the Executive Committee meeting together, selected the nominee for President-elect. No petitions were received nominating additional candidates.

President-elect

Franco Modigliani

Vice-Presidents	*Executive Committee*
Martin Bronfenbrenner	Carolyn Shaw Bell
Leonid Hurwicz	Jack Hirshleifer
James N. Morgan	Dale W. Jorgenson
Charles L. Schultze	Burton A. Weisbrod

The Secretary prepared biographical sketches of the candidates and distributed ballots in September. The Committee on Elections, consisting of Wilfrid L. David, Chairperson, Malcolm Getz, and Rendigs Fels, *ex officio*, canvassed the ballots and filed the results with the Secretary. From the Report of the Committee on Elections, I have the following information:

Number of envelopes without name for identification	180
Number of envelopes received too late	91
Number of defective ballots	16
Number of legal ballots	5,396
	5,683

On the basis of the canvass of the votes, I certify that the following persons have been duly elected to the respective offices:

President-elect (for a term of one year)
Franco Modigliani
Vice-Presidents (for a term of one year)
Martin Bronfenbrenner
Charles L. Schultze
Members of the Executive Committee (for a term of three years)
Carolyn Shaw Bell
Burton A. Weisbrod

The Secretary-Treasurer and the Managing Editors of the *American Economic Review* (George H. Borts) and the *Journal of Economic Literature* (Mark Perlman) briefly discussed written reports which had been reproduced and distributed in advance of the meeting. The Director of *Job Openings for Economists* (C. Elton Hinshaw) gave an oral report. The Chairperson of the Committee on the Status of Women in the Economics Profession (Barbara B. Reagan) summarized the written report scheduled for publication in the *Proceedings*. The President expressed gratitude to the Committee for its outstanding work.

The Secretary presented the following

resolutions which were adopted by acclamation:

> BE IT RESOLVED that this meeting record a special vote of thanks to the members of the 1974 Local Arrangements Committee headed by Richard Holton for their hard work and efficient management of the meetings of the Allied Social Science Associations.
>
> BE IT RESOLVED that this meeting commend Robert Aaron Gordon for planning a program of such unusual interest as to compete successfully against the attractions of San Francisco.

After expressing his thanks to officers and employees of the Association for their assistance during his term of office, President Heller introduced the new President, Robert Aaron Gordon, who took the chair. He announced that if the business of the meeting was not completed by 6:15 p.m. it would be adjourned until 9:30 p.m.

Under a procedural rule adopted by the Executive Committee on March 8, 1974, and communicated to the members in connection with the distribution of ballots for the 1974 election, resolutions proposed by members had to be submitted to the Secretary a month in advance of the meeting for reproduction with the signatures of the mover and the seconder. Five such resolutions had been submitted and distributed before and at the meeting.

The new President called for Theodore P. Scheinman to discuss the resolution he had submitted calling for establishment of a nonpublications membership. Since Scheinman was not present, consideration of his resolution was deferred till later in the meeting.

Four resolutions had been proposed by William H. Behn and seconded by Henry M. Levin. The President announced that in the opinion of the Association's Counsel, as well as his own, the fourth of these resolutions urging economics departments to hire Marxian economists was prohibited by the Charter of the Association and therefore out of order.[1] There was no appeal to the ruling.

The President then called upon Behn to discuss the first of the resolutions he had submitted, which read:

> We move that the American Economic Association adopt the following resolutions:
>
> WHEREAS economics students may be subject to political discrimination with regard to employment, fellowships and research grants, and being that Federal laws provide no protection against political discrimination, therefore:
>
> BE IT RESOLVED that the American Economic Association urges economics departments and faculty to follow the

---

[1] The full text of the proposed resolution follows:

We move that the American Economic Association adopt the following resolution:

WHEREAS the academic community prides itself on the free exchange of ideas, and

WHEREAS the Marxian economic paradigm has a long intellectual history, and continued study and research in this paradigm is essential to a healthy critical approach to economics, and

WHEREAS there exist circular conditions in the United States, supported by political discrimination, which inhibit the study and conduct of research of Marxian economics [i.e., the absence of permanent (tenure track) faculty teaching and conducting research in the Marxian economic paradigm—few course offerings in Marxian economics—no student research or dissertations—few Marxist scholars—the absence of permanent faculty teaching and conducting research in the Marxian economic paradigm], and

WHEREAS the appointment of visiting and temporary (one- or two-year) nontenure track faculty are inadequate measures to reverse this political discrimination in hiring and the circularity of conditions inhibiting the study of Marxian economics, therefore:

BE IT RESOLVED that the American Economic Association urges economics departments to take immediate measures to attract and hire permanent (tenure track) economists working in the Marxian economic paradigm.

Proposed by: William H. Behn, regular member of the *AEA* (address: P.O. Box 6887, Stanford, Calif. 94305)
Seconded by: Henry M. Levin, regular member of the *AEA* (address: School of Education, Stanford University, Stanford, California 94305)
November 25, 1974

> guidelines outlined below in relation to student departmental files and job search:
>
> a. Student files, including letters of recommendation, should be open to a faculty member designated by the student to examine the file for material of a political discriminatory nature.
>
> b. Departments in their placement efforts should not release information on the extradepartmental political activities of any student, nor on the intradepartmental activities that might convey information about the student's political views.
>
> c. Faculty members should refuse to respond to inquiries concerning a student's political views that arise with regard to employment, fellowships, research grants, and other opportunities for professional advancement.
>
> d. These guidelines shall be published in each issue of the American Economic Association publication *Job Openings for Economists* (*JOE*).
>
> Proposed by: William H. Behn, regular member of *AEA* (address: P.O. Box 6887, Stanford, Calif. 94305)
>
> Seconded by: Henry M. Levin, regular member of *AEA* (address: School of Education, Stanford University, Stanford, California 94305)
>
> November 25, 1974

After discussion, the resolution PASSED by a vote of 37 to 27.

The second of the resolutions submitted by Behn and Levin read:

> We move that the American Economic Association adopt the following resolution:
>
> WHEREAS Federal laws regarding equal employment opportunity require open listing of job openings, there is no publication of the economics profession listing all job opportunities making such information easily accessible. While other professional associations maintain a listing for this purpose backed by a tradition of wide participation, this is not true for the American Economic Association. There is voluntary participation by members of the American Economic Association in the publication *Job Openings for Economists* (*JOE*), but there exists no tradition of open listing of job opportunities in one convenient location. The absence of open exchange of information on job openings is particularly true of the economics departments in the most prestigious institutions.
>
> WHEREAS the American Economic Association annual meeting schedule will be advanced in the next two calendar years to October, 1975 and September, 1976 it may be expected that the hiring process for economists will further deviate from competitive market conditions including the free exchange of information. At these early dates in the academic year, departments will not have formulated hiring plans in sufficient detail to permit identification of appropriate candidates so that greater reliance on the traditional faculty network to obtain names of potential employees may be expected, particularly for placement in academic positions. Therefore:
>
> BE IT RESOLVED that the American Economic Association alter the bimonthly publication schedule of *Job Openings for Economists* (*JOE*)—currently February, April, June, August, October and December—to add publication of *JOE* in September and November, 1975 and January and November in subsequent years. Further,
>
> BE IT RESOLVED that the recommendation of the American Economic Association Executive Committee (12–27–73) that "all members of the American Economic Association have a professional obligation to list their [job] openings with the Association" (i.e., in *JOE*); and the statement that "Employers are urged by the American Economic Association to allow sufficient time (30 days) for applicant response from the time of publication in *JOE* to the time the position is filled," shall be printed at the beginning of each issue of *JOE*.
>
> Proposed by: William H. Behn, regular

member of the *AEA* (address: P.O. Box 6887, Stanford, California 94305)

Seconded by: Henry M. Levin, regular member of the *AEA* (address: School of Education, Stanford University, Stanford, California 94305)

November 25, 1974

During the discussion, it was suggested that the first two paragraphs, each beginning "WHEREAS . . . ," be deleted. Behn and Levin agreed. The President ruled that the motion be divided with separate votes on each of the two remaining paragraphs. The Director of *Job Openings for Economists* objected to the first of the remaining paragraphs as premature. He said that experience was needed to ascertain whether more frequent publication of *JOE* would be worth the cost. Andrew Brimmer also spoke against this part of the resolution. Behn moved to table it. The motion to table was seconded and passed. After further discussion, in which the incoming President-elect Franco Modigliani spoke in favor of the remaining part of the resolution, it was PASSED. As passed it read:

> BE IT RESOLVED that the recommendation of the American Economic Association Executive Committee (12–27–73) that "all members of the American Economic Association have a professional obligation to list their [job] openings with the Association" (i.e., in *JOE*); and the statement that "Employers are urged by the American Economic Association to allow sufficient time (30 days) for applicant response from the time of publication in *JOE* to the time the position is filled" shall be printed at the beginning of each issue of *JOE*.

Behn and Levin's third resolution read:

We move that the American Economic Association adopt the following resolution:

WHEREAS Federal laws on equal employment opportunity provide no protection against political discrimination in employment, and whereas there is evidence of political discrimination in termination of employment of economists on university faculty, most recently at California State University, San Jose, and Lehman College (City University of New York), procedures should be developed by the American Economic Association to assist individual members of the Association who present allegations of political discrimination in employment. Therefore,

BE IT RESOLVED that the American Economic Association shall establish a standing committee, the Committee on Political Discrimination, whose members shall be appointed each year by the President of the Association to collect information on issues of fact in cases involving termination of employment for alleged political reasons. The Committee will be called into operation upon due application by the faculty member making the allegation of political discrimination. The committee will proceed with its investigation to the best of its ability, irrespective of the cooperation of the economics department in question, and within a reasonable time period make public its report. Due consideration shall be given by the Committee to the need for timely report so as to avoid extension of the case beyond the immediate academic year. A copy of the report shall be transmitted to the individual faculty member, his or her academic department, and the institution's president, as well as to the *AAUP* for consideration in censure proceedings against the university if the findings of fact indicate political discrimination. Furthermore,

BE IT RESOLVED that if the *AAUP* censures an institution, all job openings listed in *Job Openings for Economists* (*JOE*) for the six months prior to the censure shall be relisted in *JOE* with the censure duly noted. This censure notice shall appear in all subsequent listings from this institution in *JOE* until the censure is removed by the *AAUP*.

Proposed by: William H. Behn, regular member of the *AEA*. (address: P.O. Box 6887, Stanford, California 94305

Seconded by: Henry M. Levin, regular member of the *AEA*. (address: School of Education, Stanford University, Stanford, California 94305)

Behn asked permission to make two changes in the resolution: in the first of the paragraphs starting "BE IT RESOLVED . . . " to change "faculty member" to "academic economist," and to change "economics department" to "academic department." There was no objection. Several speakers discussed the situation at San Jose State, the response of the American Association of University Professors (*AAUP*) to it, and the situation at Lehman College. Robert Eisner moved to delete the words "and within a reasonable time make public its report." After the amendment had been seconded, Behn and Levin agreed to accept it. Responding to a suggestion by the President, Behn and Levin agreed to delete the words "most recently at California State University, San Jose, and Lehman College (City of New York)" from the paragraph beginning "WHEREAS . . . ." Fritz Machlup spoke against the Association making investigations, saying that, if it is not satisfied with the actions taken by the *AAUP*, its efforts should be directed toward getting the *AAUP* to do better. Bill Taub replied to Machlup's argument. Dorothy Crook suggested deleting the words "and whereas there is evidence of political discrimination on termination of employment of economists on university faculty" from the paragraph beginning "WHEREAS . . . ." Behn and Levin accepted the change. The Director of *JOE* pointed out that institutions censured by the *AAUP* are already listed in *JOE*. He moved that the entire last paragraph and the last word of the second last paragraph ("Furthermore") be deleted. The motion was seconded. Behn and Levin accepted the change. Modigliani raised questions about the resolution, particularly pointing out the problem of insuring due process. He suggested tabling the resolution to let the Executive Committee work out the problems. Brimmer said that the Executive Committee had discussed the resolution and was sympathetic to its spirit but was concerned about the difficulties with it. He said that as a result some members of the Executive Committee had drafted a revision of the resolution, which had been reproduced and distributed at the meeting with their names on it. He moved the revised version as a substitute motion. Machlup seconded the substitute motion, which read:

> WHEREAS the American Economic Association, at its Annual (Business) Meeting on December 29, 1972, adopted a resolution opposing political discrimination by economics departments in their hiring decisions, therefore:
>
> BE IT RESOLVED that the American Economic Association shall establish a standing committee, the Committee Against Political Discrimination. The Committee shall be receptive to any allegation of political discrimination brought to it by an academic economist. If the allegation appears to have some basis, the Committee shall then urge an investigation of the allegation by the *AAUP* or by any other appropriate body. The Committee shall make its concern known to the university and economics department in question, and it shall take a continuing, active interest in the case until its resolution.
>
> JOHN G. GURLEY
> PAUL M. SWEEZY

Brimmer proposed adding "or school" to the second last line after "economics department." Machlup consented. Machlup proposed striking the paragraph beginning "WHEREAS . . . " from the substitute motion on grounds that the paragraph concerned hiring whereas the problem concerned firing. Brimmer disagreed on grounds that "hiring practices" include firing practices. Brimmer and Machlup accepted a suggestion to add the phrase "and [new paragraph] WHEREAS Federal laws on equal employment opportunity provide no protection against political discrimination in employment" between "decisions" and "therefore" in the first paragraph of the substitute motion. Sweezy explained that he and Gurley had not moved the revised version of the resolution even though their names were on it because Behn and Levin did not agree to it. He said that he would abstain from voting on the motion to substitute the revised version and expected that Gurley would also abstain. Brimmer and Machlup accepted suggestions from Gary Fromm and the President to change "the university and economics department or school in question" to "appropriate officials and governing body of the organization in question" in the second paragraph of the substitute motion. Gurley proposed deleting the word "academic" from the second sentence of the second paragraph. Brimmer and Machlup at first agreed but then changed their minds. The previous question was moved, seconded, and passed. The motion to substitute the revised version as amended was then put to a vote and lost. The previous question was again moved, seconded, and passed. The original resolution as amended was then put to a vote and PASSED. As passed, it read:

> WHEREAS Federal laws on equal employment opportunity provide no protection against political discrimination in employment, procedures should be developed by the American Economic Association to assist individual members of the Association who present allegations of political discrimination in employment. Therefore,
>
> BE IT RESOLVED that the American Economic Association shall establish a standing committee, the Committee on Political Discrimination, whose members shall be appointed each year by the President of the Association to collect information on issues of fact in cases involving termination of employment for alleged political reasons. The Committee will be called into operation upon due application by the academic economist making the allegation of political discrimination. The committee will proceed with its investigation to the best of its ability, irrespective of the cooperation of the academic department in question. Due consideration shall be given by the Committee to the need for a timely report so as to avoid extension of the case beyond the immediate academic year. A copy of the report shall be transmitted to the individual faculty member, his or her academic department, and the institution's president, as well as to the *AAUP* for consideration in censure proceedings against the university if the findings of fact indicate political discrimination.

Having ascertained that Scheinman was now present, the President announced that he was adjourning the meeting until 9:30 p.m., when Scheinman's resolution would be considered. On resumption of the meeting, the President pointed out that the whole question of "unbundling," including permitting members to pay reduced dues and receive only one journal, was under consideration by the Executive Committee. Inasmuch as the marginal cost of each journal is very low relative to average cost, the reduction in dues would be small. Scheinman then read his resolution:

> Whereas, the American Economic Association, in its December 29, 1973, business meeting adopted a resolution considering 80 percent of the dues of annual members to be payment for a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature;*
>
> Whereas, the American Economic Association does not currently have a nonpublications membership category;
>
> Whereas, the annual membership dues include payment for both publications and other activities of the Association;

Whereas, the number of annual members of the Association has declined 10 percent since its peak in 1970;

Whereas, annual dues in the Association have more than doubled since 1970;

Whereas, some members, whether for financial or other reasons, are unable to maintain their membership at the current annual rate and, therefore, must cancel their memberships either temporarily or permanently; and in so doing lose all benefits of affiliation with the Association;

Whereas, some members do not wish to receive the publications, but still wish to affiliate with the Association;

Therefore, be it resolved that the Executive Committee of the *AEA* shall initiate action to institute a new nonpublications membership category. A member in this category would not receive the *American Economic Review* or *Journal of Economic Literature*, but would receive all other membership benefits, including listing in and receipt of the membership directory, announcement of meetings, eligibility for voting in elections and eligibility for group insurance plans and charter flights. It is anticipated that this membership category carry a minimal charge of 20 percent of the annual membership dues.

Sincerely yours,
THEODORE P. SCHEINMAN

Seconded: H. Louis Stettler III

After some discussion, the resolution was put to a vote and lost.

There being no further business, the meeting was adjourned at 9:58 p.m.

RENDIGS FELS, *Secretary*

MINUTES OF THE EXECUTIVE COMMITTEE MEETINGS

Minutes of the Meeting of the Executive Committee in Washington, D.C., March 8, 1974.

The first meeting of the 1974 Executive Committee of the American Economic Association was called to order in the Washington Hilton Hotel, Washington, D.C., at 9:15 a.m. on March 8, 1974. The following members were present: Walter W. Heller, presiding, Kenneth J. Arrow, Gary S. Becker, George H. Borts, Andrew F. Brimmer, Rendigs Fels, R. A. Gordon, John G. Gurley, Robert L. Heilbroner, Guy Henderson Orcutt, Joseph A. Pechman, Mark Perlman, and Paul M. Sweezy. Irma Adelman and John Kenneth Galbraith were absent. Donald F. Turner was present as the Association's Counsel. Present as members of the Nominating Committee were James Tobin, Chairman, Allen C. Kelley, George L. Perry, Roy Radner, Christopher A. Sims, Alice Vandermeulen, and Charles Z. Wilson. Present as guests for parts of the meeting were Carolyn Shaw Bell, William C. Brainard, Robert Dorfman, Gary Fromm, Charles C. Holt, Barbara MacPhee, F. Ray Marshall, Barbara Reagan, and Robert C. Vowels.

1. *Minutes.* The minutes of the meeting of December 27, 1973, were approved as corrected.

2. *Report of the Secretary* (Fels). The Secretary reported on future meeting plans. It was VOTED to change the 1976 meetings from September 16–18 in Atlantic City to December 28–30 in Philadelphia.[1] It was agreed that the preferred dates for the meetings scheduled for 1980 in Denver were September 5–7 (Friday through Sunday), with the meeting of the Executive Committee on September 4. The Secretary reported that the questionnaires for the 1974 *Directory of Members* (formerly called the *Handbook*) had been mailed to all members. Production of the *Directory* will be computerized. The computer tape will subsequently be available for preparation of special listings. It was VOTED to establish an *ad hoc* committee on computerization of the Association's mailing list and payment records. On recommendation of the Secretary it was VOTED to cosponsor the research project of the American Political Science Association on confidentiality of research sources. It was agreed that the post of Assistant Secretary-Treasurer would henceforth be halftime during the academic year.

3. *Report of the Treasurer* (Fels). The Treasurer reported that preliminary figures from the auditors for 1973 indicated a deficit of $15,000. The deficit resulted in part from real capital losses of $127,000, $39,000 of which came from the rise in the *GNP* deflator with most of the remainder from the fall in the stock market. It was VOTED to increase dues of annual members $2 (to $23) and other dues and subscriptions proportionately effective January 1, 1975. It was VOTED to require a report from the Budget Committee in the future before considering dues increases. It was VOTED to ask the Budget Committee to study the possibility of greater progressivity in the dues structure and to report its findings to the Executive Committee on December 27, 1974. In accordance with reports described in paragraphs 4, 10, and 11 below, it was VOTED to increase the budget for 1974 by a total of $9,000, including $3,000 for the *American Economic*

---

[1] This decision was subsequently reversed by mail ballot.

Review, $5,000 for startup costs for *Job Openings for Economists*, and $1,000 for a questionnaire. It was VOTED to repeal the directive adopted by the Executive Committee at the meeting of March 11–12, 1966, establishing the policy of investing in equities all funds not needed for current operating expenses or for reserves for special grants ("Minutes of the Executive Committee Meetings") and to ask the Finance Committee to report to the next meeting of the Executive Committee its recommendation on what the policy should be.

4. *Report of the Editor of the American Economic Review* (Borts). The Managing Editor reported on his efforts to add to the Board of Editors a radical economist. It was VOTED to authorize him to appoint any one of four individuals proposed by the Executive Committee. In accordance with the Managing Editor's recommendation, it was VOTED to increase the 1974 budget for the *Review* by $3,000 to provide temporary secretarial assistance.

5. *Report of the Editor of the Journal of Economic Literature* (Perlman). The Managing Editor reported on problems relating to computerization, proliferation of economics journals and its effect on the *Journal's* costs, and accounting.

6. *Report of the Committee on the Journals* (Brainard). The Chairman reported on ways that the Association might support *Challenge* magazine. After considerable discussion, it was agreed that, while the Executive Committee believes *Challenge* meets an important need and *AEA* members have a stake in its success, any action taken should be by members of the Executive Committee in their individual capacities, since *Challenge* is a commercial venture with good prospects of success.

The Chairman recommended creation of a small committee to continuously evaluate the journals. Its function would differ from that of the boards of editors, which assist the managing editors with evaluation of manuscripts, and from that of the Budget Committee, which reviews the budgeting recommendations of the managing editors. The new committee would be concerned with overall policy and with how well the Association was meeting the needs of its members. If the managing editors need assistance on day-to-day operations, they can employ consultants. It was VOTED to establish a standing Committee on Publications.

The Chairman proposed that a questionnaire be sent to a 10 percent sample of the membership to find out how members use the journals, what their attitude is toward questions of future policy, and how well served they feel as authors or potential authors. It was agreed that this proposal should be considered a suggestion to the Committee on Publications, which was authorized to proceed with the questionnaire at its discretion.

7. *Report of the Counsel* (Turner). The Counsel discussed various ways of improving the handling of resolutions offered at the business meeting. It was VOTED to require that proposed resolutions be submitted to the Secretary at least one month in advance of the annual meeting in writing with signatures of the proposer and a second, both of whom must be members in good standing of the Association, such resolutions to be made available ahead of time. It was agreed that notice of this rule would be included with the mailing of ballots in the fall of 1974. A suggestion was made that the President announce at the beginning of the Annual Meeting his rulings on whether proposed resolutions were in order, that any appeal to his rulings be debated and voted on at that time, but that consideration of the resolutions themselves be at the end of the meeting. It was agreed that the decision on this question of timing would be left to the Counsel, the President, the President-elect,

and the Secretary. To be able to adjourn the Annual Meeting at a reasonable hour, it was agreed to schedule the Presidential Address at 7:30 p.m. instead of 8:00 p.m.

The Counsel advised clarification of the bylaw requiring that members be sent all publications of the Association. In his opinion, the bylaw refers to the *American Economic Review*, the *Journal of Economic Literature*, and the *Directory of Members* only; but in view of the proposal (see paragraph 10 below) for a new publication to be called *Job Openings for Economists*, he proposed that Paragraph 4 of Section I of the bylaws be amended to read as follows:

> 4. Every member is entitled to receive, as they appear, the following publications of the Association: the *American Economic Review*, the *Journal of Economic Literature*, and the *Directory of Members*.

It was VOTED to approve this amendment and to instruct the Secretary to submit it to the members for approval by mail ballot.[2]

8. *Nominating Committee* (Tobin). The Chairman reported the following nominees for offices in the 1974 election: for Vice-President (two to be chosen), Martin Bronfenbrenner, James Morgan, Charles Schultze, and Leonid Hurwicz; members of the Executive Committee (two to be chosen), Jack Hirschleifer, Carolyn Shaw Bell, Burton A. Weisbrod, and Dale Jorgenson. The Electoral College, consisting of the Nominating Committee and the Executive Committee meeting together, chose William Parker as representative to the American Council of Learned Societies, Orcutt as representative to the Social Science Research Council, and Franco Modigliani as nominee for President-elect.

9. *Program Committee* (Gordon). The President-elect reported on his plans for the program of the 1974 meetings. He also reported that he had received a letter from Thomas Smith concerning the bicentennial of Adam Smith and suggested that there be a session on the latter at the meetings in 1975 or 1976.

10. *Committee on the Status of Women in the Economics Profession* (Bell). It was VOTED that the Committee on the Status of Women in the Economics Profession henceforth be a standing committee of the Association. It was further VOTED to authorize the Committee to accept and expend funds for specified projects falling within its mandate with the consent of the President.

11. *Committee on Hiring Practices* (Marshall). It was VOTED to adopt the following recommendations submitted by the Chairman to implement the decision made at the previous meeting to publish job lists for economists:

> (1) The job list, to be called *Job Openings for Economists* (*JOE*), should be issued six times a year, in accordance with the committee's recommendation, as approved by the Executive Committee at its December 27, 1973, meeting.
>
> (2) The annual charge for *Job Openings for Economists* should be set at $6 per year. Subscriptions should be made available to individual members and to departments and to other organizations.
>
> (3) The President of the *AEA* should send a letter to all members of the association in April 1974 informing members about *Job Openings for Economists*, soliciting subscriptions, and alerting chairmen that they will be solicited for job listings.
>
> (4) The President should follow his letter to the membership with one to economics department chairmen, asking them to list their openings in *Job Openings for Economists*. This request should go out no later than August 15, setting September 15 as the deadline for information. This letter should contain a statement of the association's open listing policy and urge department chairmen in the strongest possible terms to

---

[2] The amendment was ratified by the members in June 1974.

list their openings. The cooperation of departments is absolutely essential to the success of this effort.

(5) An effort should be made to get the first copy of *Job Openings for Economists* in the mail by October 1, 1974, and at least by December 1, 1974.

(6) The publication of *Job Openings for Economists* should be governed by the following policies:

(a) Only members of the *AEA* may subscribe to *JOE*.
(b) No listing will be accepted containing material which violates federal civil rights laws.
(c) Listings will be accepted from institutions under censure by the *AAUP*, but the censured institutions will be noted.
(d) Jobs will be listed according to the classification of fields currently used by the *Journal of Economic Literature*.

12. *Job Market Questionnaire*. Bell and Marshall reported that a joint questionnaire to be sent to department chairmen had been drafted to provide information on the job market for the Committee on the Status of Women in the Economics Profession, *Job Openings for Economists*, the Committee on Minority Group Economists, and department chairmen. The draft needed further revision and editing. It was VOTED to approve the plan to collect data through such a questionnaire.

13. *Committee on Minority Group Economists* (Dorfman). The Chairman reported that a Summer Program for Minority Group Economists under the direction of Marcus Alexis would be held in 1974 on the campus of the University of California at Berkeley. Robert Vowels voiced the support of the Caucus of Black Economists for the summer program. The Executive Committee gave firm endorsement to the program, and various members present offered to help promote applications from students. It was VOTED to change the special Committee on Minority Group Economists to a standing Committee on the Status of Minority Groups in the Economics Profession to work with the Caucus of Black Economists and any similar organizations representing minority groups.

14. *United States-USSR Economic Conference* (Heller). The President reported on plans for colloquia of *U.S.* and *USSR* economists. An application for a $7,000 grant to the *AEA* to host the first meeting in the United States next fall or winter has been made to *IREX*. When the grant is received, the President will appoint a small committee to administer the first conference.

15. *Proposal for Accreditation*. A letter dated February 14, 1974, from Ali M. S. Fatemi to the President had been circulated to the Executive Committee in accordance with the discussion ("Minutes of the Annual Meeting, December 29, 1973") at the Annual Meeting. The letter proposed that a committee be appointed to consider taking an active role in accrediting economics departments or to establish professional standards. No action was taken.

16. *Census Advisory Committee* (Fromm). Fromm submitted for consideration three proposed resolutions on confidentiality of census data. No action was taken.

17. *Policy-Oriented Research* (Holt). Holt submitted for consideration a proposed resolution recommending that the federal government direct policy-oriented research toward national problems. It was agreed to put the resolution on the agenda of the meeting scheduled for December 27, 1974.

18. *Date of Spring Meeting*. It was agreed that the Executive Committee would meet on March 14–15, 1975, in Washington, D.C.

The meeting adjourned at 5:35 p.m.

Minutes of the Meeting of the Executive Committee in San Francisco, California, December 27, 1974.

The second meeting of the 1974 Executive Committee of the American Economic Association was called to order in the San Francisco Hilton Hotel, at 10:15 a.m. on December 27, 1974. The following members were present: Walter W. Heller, presiding, Irma G. Adelman, George H. Borts, Andrew F. Brimmer, Rendigs Fels, John Kenneth Galbraith, Robert Aaron Gordon, John G. Gurley, Robert L. Heilbroner, Joseph A. Pechman, Mark Perlman, and Paul M. Sweezy. Also present were newly elected members Carolyn Shaw Bell, Martin Bronfenbrenner, Franco Modigliani, Charles L. Schultze, and Burton A. Weisbrod. Present as Counsel was Donald F. Turner. Absent were Kenneth J. Arrow, Gary S. Becker, and Guy Henderson Orcutt. Present as guests for parts of the meeting were William C. Brainard, C. Elton Hinshaw, Fritz Machlup, Barbara MacPhee, and Barbara B. Reagan.

1. *Minutes*. The minutes of the meeting of March 8, 1974, were approved as corrected.

2. *Report of the Secretary* (Fels). The Secretary reported on future meeting plans. It was VOTED to meet on the east coast in September 1982 and in San Francisco during the Christmas holidays in 1983. For 1982, the Secretary was asked to investigate New York, Boston, and Montreal. It was VOTED to approve a contract dated February 4, 1974, with Hilton Hotels Corporation covering 1977–81 except for the paragraph on pages 3–4 concerning the 1975 meetings in Dallas.

3. *Report of the Treasurer* (Fels). The Treasurer presented a report including a budget for 1975 incorporating the recommendations of the Budget Committee. Pechman criticized the form of the budget, saying there should be three statements (cash flow, accrual, and assets and liabilities) instead of one statement mixing three kinds of information. Modigliani asked for discussion of the price of the *Index*. It was the sense of the meeting that a prepublication price of $10 be offered to members with the price otherwise set at $15 (or higher) and that the Secretary-Treasurer should explore with Richard D. Irwin, Inc., distributor of the *Index*, the suggestion to promote sales of the *Index* to economics departments and possibly to offer them a discount for purchasing all four of the volumes planned for publication in 1975. After some discussion, it was agreed to postpone a decision on when to publish a new *Directory*, in the meantime continuing to keep $50,000 a year (or a similar amount) in the budget as a reserve for it. The Chairperson of the Committee on the Status of Women in the Economics Profession (Reagan) asked that the Executive Committee appropriate $12,700 for the Committee for 1975 instead of the $5,000 in the budget. It was VOTED to appropriate $10,000. It was VOTED to raise the submission fee for the *American Economic Review* from $10 to $15. It was VOTED to raise the subscription price for *Job Openings for Economists* (*JOE*) to $12 per year except for junior members, for whom it will remain at $6. There was discussion of the policy of not paying the expenses of elected members of the Executive Committee to the annual meetings, a policy based on the expectation that their institutions will pay their expenses. It was VOTED to pay the expenses of a current member of the Executive Committee who is self-employed with the understanding that this action would not be regarded as a precedent for making other kinds of exceptions. It was then VOTED to approve the budget as amended. It was VOTED to raise dues effective January 1, 1976, to $25 for regular members, with proportional increases for other membership classes, subject to reconsideration at later meetings of the Executive Committee. It was agreed to defer until the March 1975 meeting the question of increasing the progressivity of the dues structure. In accordance with the sense of the meeting, Fels and Brimmer determined the following wording for a directive to the Finance

Committee to replace the one repealed last March:

> Funds of the Association not needed for current operating expenses or reserves for special funds shall be invested with due regard for yield, liquidity, and safety.

4. *Report of the Editor of the American Economic Review* (Borts). On recommendation of the Managing Editor of the *American Economic Review*, it was VOTED to renominate Anna Schwartz to the Board of Editors and to nominate Eugene Fama, Robert J. Gordon, James Melvin, and William Nordhaus. The Editor reported that 25 percent of the authors of articles in the December 1974 issue of the *Review* were not members of the Association. He inquired about the appropriateness of his writing to them suggesting that they become members. It was agreed that such letters should be sent by the Secretary.

5. *Report of the Editor of the Journal of Economic Literature* (Perlman). On recommendation of the Managing Editor of the *Journal of Economic Literature*, it was voted to nominate Moses Abramovitz, Arthur Goldberger, Thomas Mayer, and Ryuzo Sato to the Board of Editors.

6. *Report of the Committee on Publications* (Brainard). The Chairperson reported that the Committee on Publications had decided to proceed with the market survey authorized last spring. Although, as part of a research project for the National Science Foundation, Machlup will make a pilot study of the extent to which journal articles are read, which will be useful to the Committee, the study will not yield all the specific information needed by the Association to make decisions about cutting costs. Machlup requested free use of the Association's mailing list for his study. It was agreed to grant the request. The President-elect asked that the two editors report to the March meeting what they would do if required to cut costs 10 percent. Modigliani suggested polling the members on whether they would be willing to pay more to have the *Directory* published every three years instead of every four or five. Brainard said that the survey to be carried out by the Committee on Publications could include a question on this matter.

7. *Report of the Director of Job Openings for Economists* (Hinshaw). The Director of *Job Openings for Economists* (*JOE*) reported that the new publication was off to a good start. Bell asked that the Executive Committee be given a separate accounting of the costs and revenues of *JOE*.

8. *Report of the Chairman of the 1975 Program Committee* (Modigliani). The Chairman of the 1975 Program Committee reported on his plans. There was discussion of the advisability of the October dates for the 1975 meetings. It was the sense of the meeting that the dates should be shifted to the traditional period between Christmas and New Year's if feasible. The President appointed a committee to investigate the feasibility of such a shift consisting of Fels as chairman, Galbraith, Ralph Green, MacPhee, Modigliani, and Reagan.

9. *Report of the Counsel* (Turner). The Counsel gave his opinion as to which of the resolutions to be considered at the Annual Meeting on December 29, 1974, were in order. He also stated that an amendment within the subject matter of the resolution would be in order. It was VOTED to extend his term of office.

The meeting was adjourned at 5:10 p.m.

RENDIGS FELS, *Secretary*

REPORT OF THE SECRETARY FOR 1974

Annual Meetings. At the request of the Executive Committee, the dates of the 1975 annual meetings in Dallas have been changed from early October to December 28–30. The Employment Center will begin operations December 27 to give those concerned a greater opportunity to attend the sessions scheduled for December 28–30. The schedule for subsequent meetings is: September 16–18, 1976, Atlantic City, Chalfonte-Haddon Hall; December 28–30, 1977, New York, New York Hilton Hotel; August 29–31, 1978, Chicago, Conrad Hilton Hotel; December 28–30, 1979, Atlanta, Atlanta Hilton and Peachtree Center Plaza; September 5–7, 1980, Denver, Denver Hilton Hotel; and December 28–30, 1981, Washington, D.C., Washington Hilton Hotel and Sheraton-Park Hotel. The 1982 meetings will be held in the vicinity of Labor Day at an eastern city to be determined. Negotiations are underway with a view to meeting in San Francisco, December 28–30, 1983.

Membership. Table 1 shows that at the end of 1974 the total number of members and subscribers had nearly regained the peak reached at the end of 1970 just before dues and subscriptions were doubled in price. Even though the price of subscriptions was subsequently raised another 55 percent, the number of subscribers is now greater than in 1970. In contrast, though the subsequent increase in dues was only 5 percent, the number of members is still below the peak. Demand is inelastic for both members and subscribers, especially subscribers. The fall has been especially marked for annual members. The number of junior members, whose dues are only half as great as the dues of annual members, has increased 50 percent.

TABLE 1—MEMBERS AND SUBSCRIBERS
(End of Year)

	1970	1973	1974
Class of Membership			
Annual	16,075	14,453	14,544
Junior	2,077	2,480	3,135
Family	289	277	313
Complimentary	160	413	418
Life	291	332	342
Honorary	16	14	14
Total Members	18,908	17,969	18,766
Subscribers	7,265	7,228	7,353
Total Members and Subscribers	26,173	25,197	26,119

Directory. The 1974 *Directory of Members*, formerly called the *Handbook*, was published and distributed to members late in the year. It contains biographical and bibliographical information. The information is on a computer tape, and a program has been written to make possible the preparation of special lists for special purposes.

Employment Services. The National Registry for Economists continues to be operated on a year-round basis by the Illinois State Employment Service under the direction of Mrs. Theresa Scholl. This is an automated retrieval service in which the anonymity of employers is maintained. All economists looking for jobs are urged to register. The Association is indebted to Mrs. Scholl not only for the Registry but also for her expert assistance and supervision of the employment service provided at the annual meetings of the Allied Social Science Associations by the state offices of the U.S. Employment Service. During 1974, the Association inaugurated publication of *Job Openings for Economists* and discontinued the "Vacancies and Applications" section of the *American Economic Review.*

Permission to Reprint and Translate. Official permissions to quote from, reprint, or translate and reprint articles from the *American Economic Review* and the *Journal of Economic Literature* totaled 180 in 1974 compared to 147 in 1973. In addition permission was granted to reprint 22 abstracts from the *Journal.* Upon receipt of a request for permission to reprint an article, the publisher or editor making the request is instructed to get the author's permission in writing and send a copy to the Secretary as a condition for official permission. The Association suggests that authors charge a fee of $150, but they may charge some other amount, enter into a royalty arrangement, waive the fee, or refuse permission altogether.

Visiting Economics Scholars Program. A Visiting Economics Scholars Program, modeled on the Visiting Scientists Program in Economics formerly supported by the National Science Foundation, was inaugurated for the academic year 1974–75 under the direction of the Assistant Secretary, C. Elton Hinshaw. Its purpose is to facilitate visits by leading economists to smaller colleges emphasizing teaching. The colleges are expected to pay part or all of the costs of the visits in accordance with their financial resources; at a minimum they take care of the local expenses of the visitor. Inquiries should be directed to the Assistant Secretary.

Committees and Representatives. Listed below are those who served the Association during 1974 as members of appointed committees or as representatives. Years in parentheses indicate the final year of the term to which they most recently have been appointed. On behalf of the Association, I wish to thank all of them for their service.

Standing Committees

ADVISORY COMMITTEE ON THE HISTORY OF THE ASSOCIATION

George J. Stigler, *Chairperson*
Joseph Dorfman
Harold F. Williamson, *Corresponding Secretary*

BUDGET COMMITTEE

Joseph A. Pechman, *Chairperson* (1974)
Irma Adelman, *Chairperson* (1975)
Andrew F. Brimmer (1976)
*Burton A. Weisbrod (1977)
Rendigs Fels, *Ex Officio*
Walter W. Heller, *Ex Officio* (1974)
R. A. Gordon, *Ex Officio* (1975)

REPORT OF THE TREASURER FOR THE YEAR ENDING DECEMBER 31, 1974

The table on the next page gives budget data for 1973, 1974, and 1975. The budgets are compared with the actual results for 1973 and with the results anticipated for 1974 at the time (December 27, 1974) that the 1975 budget was approved by the Executive Committee. The actual results for 1974 are given below in the financial statements following the auditor's report. Since the Treasurer's Report is sent to the printer before the audit takes place, the final results cannot be known at the time this report is written.[1] Ordinarily actual results differ from anticipated by a significant margin. Nevertheless, it is clear that a very large deficit was incurred in 1974 and an even larger one is in prospect for 1975.

The 1974 deficit resulted from a shortfall of investment income from the decline in the stock market, spending on the periodicals above the budgeted amounts because of unexpectedly large increases in paper and printing costs, the decisions by the Executive Committee in March 1974 to launch a new publication (*Job Openings for Economists*) and make the post of Assistant Secretary-Treasurer half-time, and a planned deficit of $10,000 in the budget adopted by the Executive Committee on December 27, 1973.

The most important reason for the deficit was real capital losses. Under the formula used by the Association for calculating income from investments, real capital gains and losses are included whether realized or not. To the extent that gains or losses are from stocks, they are spread over three years. The net loss for 1974 includes a gain of $25,069 carried forward from 1972; a loss of $58,509 carried forward from 1973; part of the real capital losses incurred during 1974 (the part to be recognized in 1974); and dividends and interest. The rise in paper and printing costs is second only to the investment losses in accounting for the deficit. Some increase had been anticipated in the budget approved on December 27, 1973, but the actual increase turned out to be much greater.

The line item for *Job Openings for Economists* (*JOE*) understates its cost because it does not include salaries. *JOE* is eventually expected to become self-supporting, but start-up costs and temporary subsidization of operating expenses contributed about $12,000 to the expected deficit for 1974.

The projections of revenues and the proposals for expenditures for 1975 indicate a deficit on the order of $155,000.[2] There is no provision in the budget for contingencies. Actual results are usually worse than expected.

The expected deficit of $155,000 is on what might be called an accrual basis. The figure includes $99,000 of investment losses to be carried forward from 1973 and 1974. It also includes a reserve for a new *Directory* in 1977 (or some later year) of $50,000. On the other hand, it omits $55,000 representing the manufacturing cost of four volumes of the *Index of Economic Articles* scheduled for publication in 1975. It is expected that the manufacturing costs, which will be borne by the Association, will be recovered in subsequent years by sales. It therefore has not been included in the budget shown in Table 1, but it will require a cash outlay.

---

[1] Some changes, however, have been made in galley proof, including the addition of this and other footnotes and revision of the projections of revenues in Table 1.

[2] At its meeting on March 14, 1975, the Executive Committee took a number of actions to improve the financial position of the Association. Although many of them will have no effect until 1976, the size of the expected deficit for 1975 would be markedly smaller if these actions were taken into account.

[a] As approved by the Executive Committee, December 17, 1973. Does not include additional expenditures authorized March 14, 1974.

[b] Estimates prepared November 5, 1974, of revenues and expenses for the entire year.

[c] The projections of revenues for 1975 were revised in March in the light of the actual results for 1974. The estimates of expenditures take account of the actions by the Executive Committee at its meeting of December 27, 1974, and by the membership at the Annual Meeting of December 29, 1974. Actions taken by the Executive Committee at its meeting on March 14, 1975, however, have not been incorporated in the estimates of revenues and expenditures.

Adjusting for these three items (investment losses of past years, the reserve for the *Directory*, and the manufacturing cost of the *Index*) results in a cash flow deficit of $76,000.

Neither of the two deficits estimated above measures the change in the net worth of the Association. Since the Association is not under obligation to publish a new *Directory* in 1977 or any other year, setting aside a reserve of $50,000 does not change the net worth. Neither does the $55,000 to be spent on manufacturing the *Index* (provided the money is recovered with interest from sales of future years). The investment losses carried forward from 1973 and 1974 likewise do not represent a change in the net worth of the Association between January 1 and December 31, 1975, even though they are recognized in that year. Therefore, the net worth of the Association is expected to rise (not fall) in 1975.

The accrual deficit, the cash deficit, and the rise in net worth are all relevant to the financial problems of the Association but in different ways. Of the three, the accrual deficit is the one of greatest importance for budget decisions. The practice of recognizing only one-third of the real capital losses incurred from equities in the year in which they occur allows for the vagaries of the stock market. The losses of 1973 (and 1974) not recognized in that year did not affect that year's budget decisions, but the corollary is that they should affect later decisions. Although there is no legal obligation to publish another *Directory*, spending decisions must take account of the likelihood that some future Executive Committee will want one.

The size of the deficits that may be regarded with equanimity depends in part on the ratio of net worth to annual expenditures. At the end of 1973, the net worth was $162,338, not counting $80,000 in the reserve for the 1974 *Directory* which has now been spent (but was not counted as part of the 1974 deficit). The ratio of this figure to the expenditures of 1974 is less than 0.3. Since then the net worth has gone down. It was negative at the end of 1974.

Another criterion for the financial position is the size of the net worth relative to the largest previous deficit. By this test, the deficits of 1974–75 are excessive. The largest deficit ever incurred by the Association was in 1970. It was $242,000—a figure in excess of the net worth at the end of 1973.

In my opinion, the Association should aim for surpluses on the order of $100,000 in 1976 and later years until its net worth rises to an adequate ratio to expenditures. Continuing inflation will raise annual expenditures year by year even if no new programs are undertaken and no old ones expanded. With an annual budget in excess of $800,000 a year and an inflation rate of 5 percent, the net worth would need to rise $20,000 a year even if it were initially adequate, which it is not; and with an inflation rate of 10 percent, the net worth would need to rise $40,000 a year. Increased revenues will be needed to compensate for inflation and to maintain and increase net worth.

Under action taken by the Executive Committee on March 8, 1974, the dues of regular members increased from $21 to $23 on January 1, 1975, with other dues and subscriptions rising in the same proportion. In view of the expected deficits for 1974 and 1975, the Executive Committee on December 27, 1974, voted to increase the dues further to $25 for regular members (and proportionate increases for subscriptions and other classes of membership) effective January 1, 1976. These actions were taken in accordance with a provision of the bylaws permitting the Executive Committee to raise dues in proportion to the rise in relevant wage and price indexes, provided that the increase not exceed 10 percent in any one year. They will not be sufficient to make the financial position of the Association sound unless the stock market makes an astonishing recovery. Under the circumstances, either further increases in dues, requiring a change in the bylaws approved by vote of the members, or significant cuts in expenditures to the detriment of the services rendered to the members will be necessary.

RENDIGS FELS, *Treasurer*

REPORT OF THE FINANCE COMMITTEE*

The accompanying inventory lists the securities held by the American Economic Association as of December 31, 1974, with costs and market values as of that date. The total market value of the securities portfolio at year end was $426,186. After making adjustments for cash additions and withdrawals, we estimate that the Association's investment portfolio (on a total return basis) declined in value by 28.5 percent during 1974. In comparison, although the widely quoted market indices were down 24 percent to 27 percent on the same basis last year, a more representative picture of the extent of the past year's market decline is provided by an unweighted average of all of the stocks on the New York Stock Exchange which was down 33.1 percent** in 1974. On a longer term basis, from the end of 1967 through December 31, 1974, which is a period encompassing contracting and expanding economic environments and up and down market cycles, the account's total return was +2.7 percent, while the Dow Jones Industrial Average, using comparable total return figures, was off 10.6 percent and the unweighted average of New York Stock Exchange stocks dropped 50.1 percent.**

It should be remembered that the $426,186 figure referred to above includes a Special Grant that was made by the Ford Foundation in January of 1969 and subsequently commingled with the Association's account. As of December 31, 1974, the Association's portion of the aggregate account was $298,143, or 70 percent, and the Special Grant represented the remaining $128,043, or 30 percent of the total.

During the past twelve months, several changes were made in the equity component of the account. This involved the sale of 500 Houston Lighting and Power, 1,500 Westinghouse Electric, 700 Newmont Mining, 300 Chase Manhattan Corporation, 1,000 Hawaii Bancorporation, 1,200 Kewanee Oil, and $15,000 par value Husky Oil convertible bonds; and new purchases of 600 Citicorp, and 1,200 Gulf Oil Corporation while additions in the following amounts were made to existing holdings: 100 Eastman Kodak, 200 First Bank Systems, 100 Merck, and 100 Xerox. The portfolio restructuring process carried out over the past two years has also had the effect of increasing the investment income of the portfolio by $5,335 or 43 percent.

Looking over the year just concluded, it

* More than one cost basis.

is important to note that there were an unusual number of developments, most of which were unprecedented and largely unpredictable. The most damaging of these events were the Arab oil embargo and the resulting high price of oil, the political turmoil culminating in the resignation of the Vice-President and President, the financial strains which appeared in the international monetary community, and the adverse weather conditions in the farm belt that led to disappointing crops and higher food prices. As a result of these difficulties, interest rates (which were also affected by the government's restrictive monetary policy) and the pace of inflation rose to unprecedented peacetime levels.

These developments exerted downward pressure on the equity markets causing investor confidence to fall to an extremely low level and stocks to sell at their lowest valuation in more than thirty years. Although 1975 will clearly be a recessionary year, the managers of the Fund anticipate that this continued slowing in economic activity will bring with it lower rates of inflation and a more moderate level of short-term interest rates and that an economic recovery will begin late in 1975. They further believe that, with security prices relative to underlying book value, earnings and cash flow extremely depressed, many of the uncertainties which exist today have been discounted and that any positive developments, such as those alluded to above in the areas of inflation and interest rates, could generate an upward revaluation of equities. However, the Fund managers do not expect investor confidence to be fully restored until meaningful progress is made with respect to the Middle East situation in general and a reduction in the price of oil in particular.

In view of this, we are persuaded that no change should be made at this time in the Committee's basic policy of maintaining a meaningful exposure to equities. However, recognizing that important questions—perhaps the most significant of which are the oil, political, and military aspects of the Middle East situation—are not yet fully resolved, we will continue to reevaluate the Association's investment position; and, should conditions warrant a change in the portfolio's composition, appropriate steps will be taken.

BERYL W. SPRINKEL, *Chairperson*

AUDITORS' REPORT

To the Executive Committee of
The American Economic Association:

We have examined the statements of assets and liabilities of THE AMERICAN ECONOMIC ASSOCIATION (a District of Columbia corporation, not for profit) as of December 31, 1974 and 1973, and the related statements of revenues and expenses, changes in general and restricted fund balances and changes in assets and liabilities for the years then ended. Our examination was made in accordance with generally accepted auditing standards, and accordingly included such tests of the accounting records and such other auditing procedures as we considered necessary in the circumstances.

In our opinion, the accompanying statements present fairly the assets and liabilities of The American Economic Association as of December 31, 1974 and 1973, and its revenues and expenses, changes in fund balances and the changes in its assets and liabilities for the years then ended, in conformity with generally accepted accounting principles consistently applied during the periods.

ARTHUR ANDERSEN & CO.

Memphis, Tennessee,
February 27, 1975.

THE AMERICAN ECONOMIC ASSOCIATION
NOTES TO FINANCIAL STATEMENTS

(1) Significant Accounting Policies:

Investments—

The Association accounts for its investments on a market value basis. Under the method used by the Association to value investments, the change in market value of corporate stocks during the year, after adjusting for an inflation factor (11.8 percent in 1974 and 7.0 percent in 1973), is recognized in income over a three-year period. The change in market value of corporate bonds and obligations, after adjusting for the inflation factor, is reflected in income currently. The changes in market value of investments are allocated to the general and restricted fund balances as appropriate.

Accrual for Directory—

Approximately every three to five years, the Association publishes a Directory which lists, among other things, the names and addresses of its membership. This Directory was published in 1974 and distributed at no cost to the membership. In order to more properly match the publishing cost of this Directory with revenue from membership dues, the Association has provided annually a reserve for estimated publishing costs. Actual costs of $68,780 in excess of accrued amounts at the beginning of the year were expensed currently.

Deferred Income—

Revenue from membership dues and subscriptions to the various periodicals of the Association are deferred when received, with these amounts then recognized as income quarterly as publications are mailed to the members and subscribers.

Life membership dues are also deferred when received, with subsequent recognition as income over the estimated average life of these members.

(2) Investments and Investment Income:

The following is a summary of investments held by the Association at December 31:

	1974		1973	
	Cost	Market	Cost	Market
Corporate bonds and obligations	$438,000	$438,000	$209,750	$210,500
Corporate stocks	410,753	391,174	445,938	565,523
	$848,753	$829,174	$655,688	$776,023

Investment gains (losses) recognized in income for the years ended December 31 were as follows:

	1974	1973
CORPORATE BONDS AND OBLIGATIONS—		
Interest	$ 23,720	$13,270
Decline in market value	(11,680)	(6,649)
	12,040	6,621
CORPORATE STOCKS—		
Cash dividends	16,256	12,943
Decline in market value recognized (Note 3)	(117,154)	(20,277)
	(100,898)	(7,334)
OTHER—		
Investment losses allocated to a restricted fund (Note 4)	32,799	1,848
INVESTMENT GAINS (LOSSES) INCLUDED IN INCOME	$ (56,059)	$ 1,135

(3) Unrecognized Change in Market Value of Investments:

As described more fully in Note (1), the Association recognizes in income over a three-year period changes in the market value of its corporate stocks. The following summarizes the years in which market value changes in stocks occurred that affect 1973 and 1974 revenues, and the amount of these market value increases (declines) that will be recognized in income in future periods.

Year of Market Value Change	Recognized In Income In		To Be Recognized In		Unrecognized Change as of December 31	
	1973	1974	1975	1976	1974	1973
1971	$ 13,163	$ —	$ —	$ —	$ —	$ —
1972	25,069	25,069	—	—	—	25,069
1973	(58,509)	(58,509)	(58,509)	—	(58,509)	(117,018)
1974	—	(83,714)	(83,714)	(83,715)	(167,429)	—
	$(20,277)	$(117,154)	$(142,223)	$(83,715)	$(225,938)	$ (91,949)

Included in the above unrecognized changes as of December 31 are declines of $68,007 and $27,677 in 1974 and 1973, respectively, which have been allocated to a restricted fund. The amounts allocated are based on the percentage of the Association's total stock portfolio owned by this restricted fund.

(4) Restricted Fund:

In 1968, the Association entered into an agreement with the University of Colorado relating to the Ford Foundation grant for the Economics Institute which provides, among other things, that the Association invest a portion of the funds received and allocate any income and market value adjustments therefrom to the restricted fund. In accordance with this agreement, the following adjustments were allocated to the restricted fund:

	1974	1973
Net investment (losses) (Note 2)	$(32,799)	$(1,848)
Market value adjustments arising from inflation	21,773	16,643
	$(11,026)	$14,795

(5) Retirement Annuity Plan:

Employees of the Association are eligible for participation in a contributory retirement annuity plan. Payments by the Association and participating employees are based on the employee's compensation. Benefit payments are based on the amounts accumulated from such contributions. The total pension expense was $6,798 and $5,355 for 1974 and 1973, respectively.

(6) The Association:

The American Economic Association is an educational organization, substantially exempt from income tax under section 501(c)(3) of the U.S. Internal Revenue Code. As required by Section 511(a) of this Code, the Association provides for Federal income taxes on certain revenues which are not substantially related to its tax exempt purpose. This "unrelated business income" includes income from advertising and the sale of mailing lists.

The Association has been determined to be an organization which is not a private foundation.

EXHIBIT I—THE AMERICAN ECONOMIC ASSOCIATION
STATEMENTS OF OTHER GENERAL AND ADMINISTRATIVE EXPENSES
FOR THE YEARS ENDED DECEMBER 31, 1974 AND 1973

	1974	1973
Mailing list file maintenance and periodic mailing expenses	$13,598	$14,205
Accounting and legal	7,500	7,300
Office supplies	8,998	5,507
Postage	11,475	5,383
Dues and subscriptions	2,800	3,325
Telephone	3,130	3,063

Investment counsel and custodian fees	2,783	2,865
President and president-elect expenses	4,200	2,334
Travel and entertainment	1,327	1,084
Depreciation (straight-line method)	737	800
Uncollectible receivables	586	262
Currency exchange charges (credits)	(55)	193
	$60,450	$49,321

REPORT OF THE MANAGING EDITOR AMERICAN ECONOMIC REVIEW

The number of manuscripts submitted in 1974 was 723, slightly less than last year, and approximately the same as in 1972. We printed 125 papers in all, 14 more than last year. The comparative statistics for the last twenty years are shown in Table 1.

Manuscripts Submitted, Accepted, and Published

The flow of manuscript submissions appears to be at a plateau of 700 to 800 a year, a level reached in 1969. This is double the number submitted ten years ago, and roughly three times the level of the mid-1950's. The present format of the *Review* easily permits publication of 110 to 140 papers a year, which also doubles the publication rate reached ten years ago. Nevertheless, we continue to publish only 16 to 20 percent of the papers submitted. The high rejection rate is not due to limitations imposed by the format. It springs instead from the combined result of refereeing and editorial decisions. I suspect that many rejected papers are reworked and ultimately published elsewhere. From conversations with other journal editors and from my reading of other journals, I do know that we publish each other's rejected papers. A potential author benefits from the diversity of tastes and perceptions exercised by the different journals.

TABLE 1—MANUSCRIPTS SUBMITTED AND PUBLISHED, 1954–74

Year	Submitted	Published	Ratio of Published to Submitted
1954	231	47	.20
1955	245	41	.17
1956	242	48	.20
1957	215	40	.19
1958	242	46	.19
1959	279	48	.17
1960	276	46	.17
1961	305	47	.15
1962	273	46	.17
1963	329	46	.14
1964	431	67	.16
1965	420	59	.14
1966	451	62	.14
1967	534	94	.18
1968	637	93	.15
1969	758	121	.16
1970	879	120	.14
1971	813	115	.14
1972	714	143	.20
1973	758	111	.15
1974	723	125	.17

The backlog of accepted papers is the same as last year. As of November 30, there are 81 accepted papers which have not yet been published. Twenty-nine will appear in the March 1975 issue, the remaining 52 in June or September 1975.

We printed 125 papers this year, 49 main articles and 76 shorter papers. The latter include short articles, notes, comments, replies, and special obituaries. The special obituaries are written at my request to take note of the role which a number of individuals have played in the history of economic analysis.

As shown in Table 2, the size of the *Review* has been kept to 1,146 pages, the same as last year. The size of the December issue was kept under control by a reduction in the number of pages devoted to the Ph.D. dissertations, from 67 last year to 25 in 1974. The reduction was made possible by the elimination of the 75-word abstract. We now print only the author's name, institution, year, and title, classified by field. The abstracts are available in a publication of University Microfilms, which most university reference libraries can obtain. It seemed to be a waste of

TABLE 2—SUMMARY OF CONTENTS, 1973 AND 1974

	1973		1974	
	Number	Pages	Number	Pages
Articles	54	747	49	684
Shorter Papers, including Notes, Comments, and Replies	57	273	73	386

space to publish them in the *Review* as well. The *Review* will continue to publish the annual dissertation list.

Subject Matter of Submitted and Printed Manuscripts

Table 3 shows the subject matter distribution of submitted and printed manuscripts. The most popular fields are microeconomics, macro and monetary theory, international economics, labor economics, and welfare economics. These six fields comprise 60 percent of the papers submitted and papers published.

I have continued the practice of inviting papers on subject matter of special interest. In 1973 and 1974, the *Review* published the Nobel Prize addresses by Simon Kuznets, Kenneth Arrow, and Wassily Leontief. In 1973, we published an invited paper by Don Patinkin on the work and teaching of Frank Knight. In 1974, we published four invited reviews of the annual report of the Council of Economic Advisors (*CEA*) and an invited review of the 60th Annual Report of the Board of Governors of the Federal Reserve System. In 1975, we will continue to publish re-

views of the *CEA* report, but will invite a smaller number.

Anonymous Refereeing

Beginning January 1974, all papers have been refereed anonymously. Authors are requested to omit their name and institutional affiliation from the title page and title footnote. The practice was discussed in my report last year. It was adopted to make certain that knowledge of the author's identity or employer's identity would play no role in evaluation of the paper.

Only one referee out of some 400 has objected to the practice and refused to read a paper because the author was not identified. No other objections have occurred. If referees comment at all on the practice, it is favorable. Occasionally a referee requests the name of the author after the evaluation is carried out. We will provide that information. A referee may know the author's identity, either through prior reading of the paper, or through repeated self-referencing in the text. So far I don't have the impression that self-referencing is carried out for the purpose of piercing the veil of anonymity.

Expenses—Printing and Mailing

The 1974 costs of printing and mailing the *Review* are shown in Table 4 and for other years in Table 5. The net number of pages includes only those pages listed in our table of contents plus the index. Advertising pages then make up the difference between gross and net. The 1974

TABLE 5—ACTUAL AND BUDGETED EXPENDITURES, 1967–1975

	Printing and Mailing	Payments to Contributors	Office Expenses	Total
1967	$ 82,840	$2,255	$27,114	$112,209
1968	92,948	2,140	29,155	124,243
1969	97,183	600	26,765	124,548

1974 (actual)[a]	139,502		58,396	197,898
1975 (budget)	165,742		65,911	231,653

[a] Estimate.

printing expenses exceed the estimate I made last December for a number of reasons: in 1974, 4,500 more copies were printed than in 1973; mailing costs rose; a paper surcharge has been added to the regular printing contract to reflect the increased price of this material; and an across-the-board increase in other printing charges took effect with the September issue. In all, our 1974 printing and mailing costs will come to $139,501, an excess of $18,000 over the budgeted figure for this year. I expect printing costs to rise again in 1975. There are two reasons: the increases in the printing contract and in mailing charges have not been in effect for one full year. Moreover, another increase in printing costs may occur and it would be desirable to appropriate funds for this contingency. Of course, the current business recession may permit us (in the short run) to withstand a request for an increase by taking advantage of the greater degree of aggressive rivalry among printing companies.

Charges to Authors

Continued increases in costs of printing are a matter of concern because they are eventually reflected in higher membership dues. Other ways to defray printing costs require a direct levy on the author or prospective author. Some journals have used a page charge to reduce the share of the cost falling on the readers. This practice would appear most practicable in those fields where research receives outside financial support and the page charge ultimately comes out of a research contract or grant. Research support in economics may not be sufficiently widespread to allow page charges. But it should not be ruled out for future consideration. Another type of levy on the author is the submission fee. At the moment, the *Review* charges a ten dollar fee. The proceeds are used to pay for manuscript screening. This was described in my annual report for the year 1971. Other journals in economics also use submission fees, and some may devote the proceeds to production costs. This practice could become more widespread in the future.

Office Expense

Office expenses rose in 1974 because of higher salaries, increased supply costs, higher fringe benefits, and additional editorial assistance. The 1974 figure shown in Table 5 is still an estimate as all charges are not yet in. Further increases in office expenses will occur in 1975 as a consequence of increased personnel and material costs.

Board of Editors

Five members of the Board of Editors complete their terms at this time: Robert Baldwin, Jack Hirschleifer, Sherwin Rosen, Thomas Saving, and Anna Schwartz. I wish to thank them for their hard work, cooperation, and critical standards.

I am submitting to the Executive Committee the names of four nominees to serve three-year terms until December 31, 1977. They are: Eugene Fama, Robert J. Gordon, James Melvin, and William Nordhaus. Anna Schwartz has graciously accepted a second term.

I should like to express my thanks to the continuing members of the Board of Editors: Bela Balassa, Martin Feldstein, Ann Friedlaender, Stephen Goldfeld, Robert Hall, Bent Hansen, Leonard Rapping, Stephen Resnick, Jerome Stein, Joseph Stiglitz, S. C. Tsiang, Finis Welch, and Marina Whitman. I appreciate their work and assistance.

The following assisted me this year as editorial consultants: Raveendra Batra, Ernst Berndt, Roger Betancourt, Alan Blinder, Byron Brown, Allan Feldman, Donald Frey, Paul Ginsburg, Gerald Goldstein, Michael Grossman, William Haley, James A. Hanson, Jerry Hausman, John Kennan, Rachel McCulloch, James Ohls, Mark Pauly, J. David Richardson, John Roberts, Robert Rohr, José Alexandre Scheinkman, John Taylor, and Warren Weber.

I have received valuable proofreading and mathematical assistance from: Clemens F. J. Boonekamp, Kenneth Chang, Robert Jones, Chon Pyo Lee, Hiroshi Ono, and Orlando Roncesvalles. Finally, I am grateful to Wilma St. John for her fine work as assistant editor, and to Carol Chapin, editorial assistant.

In addition to the members of the Board and the editorial consultants, I have sought and received the assistance of a large number of economists during the course of the year. I wish to thank them for their cooperation and application of high standards in reading and evaluating manuscripts. They have eased the work load that would have otherwise fallen on the Board of Editors. The following have assisted in this way:

GEORGE H. BORTS, *Managing Editor*

REPORT OF THE MANAGING EDITOR JOURNAL OF ECONOMIC LITERATURE

This year represents the end of my second term as managing editor. Accordingly, it seems appropriate to sketch what my staff and I have undertaken during these past six years, to discuss what has happened in 1974, and to suggest some of the things with which we are concerned for 1975.

Six-year Review

When the *Journal of Economic Literature* was established, the objective was to have a journal primarily concerned with the literature in economics. The plan was to divide the effort basically in two parts:

I. There was to be a limited number of articles on emergent trends in the literature. These included:
   (1) Comprehensive surveys of literature developed within the prior decade or so in subfields.
   (2) Interpretive essays on subfields.
   (3) Miscellaneous elements such as articles on trends in literature, etc.

II. There was to be a major bibliographic effort, including:
   (1) The absorption of the new book listing and reviewing function of the *American Economic Review*. This absorption involved a changing from listing books, as in the *AER*, to providing brief annotations and classification of them in accordance with the American Economic Association 2-digit classification system.
   (2) The absorption of the *Journal of Economic Abstracts* and of the *Index of Economic Articles*. In this connection we were directed to:
      (*a*) Use in the *Journal of Economic Literature* the 2- and 3-digit classification system developed by the Classification Committee of the American Economic Association in 1967.
      (b) Publish abstracts.
      (c) Develop a compatible fourth digit to be used for classification for the annual *Index of Economic Articles*.
      (d) Prepare the annual *Index of Economic Articles*.

Articles

Our plan has been to publish four survey articles each year. In some instances we have published only three or even two, either because articles which had been assigned did not appear in publishable form or because, as in 1974, there was an opportunity to publish a commemorative article. That 1974 opportunity seemed to serve a double purpose; not only did it result in what is clearly a significant contribution itself, but it also drew attention to an earlier article of particular historical importance. We have also published a variety of articles on the literature, some review articles on particularly noteworthy books, and several articles about the development of economic literature, as well as some communications which are largely an outgrowth of reactions to our survey articles.

Books

We have annotated 1,200–1,300 books per year, classified in thirty-six categories, as well as all new journals (or older ones not previously covered). Reviews of about 170–185 books per year are published.

Journals

Journal Selection

The directive to absorb the *Journal of Economic Abstracts* and continue *Index of Economic Abstracts* meant that there was no option in the initial selection of journals. The records sent us from John Gurley's *American Economic Review* office, which maintained the list, showed that it received 254 journals for listing purposes in the *Journal of Economic Abstracts*. In addition, there were another thirty-five journals included in the *Index of Economic Abstracts* but not listed in the *Journal of Economic Abstracts*. The annual *Index* was to be compiled from our quarterly data and from volumes of collected essays and Congressional documents.

As time has passed, we have reduced the number of these old, inherited agreements in order to make space for new or other journals, as well as eliminated some which seemed to be inappropriate. In our six years we have tried to maintain a reasonable relationship between dropping earlier listings and abstracting agreements and adding new ones. You will note, later on when we come to Table 1, that we have listed the contents (in whole or in part) of 986 journal issues (drawn from 219 journals) in the four issues published during 1974. This shift represents a reduction from the 1,011 journals handled in 1973, but it is also an increase of some significance over the number of journals we handled in the first three years of our existence.[1] The plain fact that journals are proliferating in number poses a burden on our earlier decision to list and abstract where we thought appropriate.

Those journals which are listed but are only in part economics in content are selectively listed. We have also ceased to classify articles in foreign languages in the absence of an English summary or abstract because of the difficulties of finding personnel.

Abstracts

In the interest of cost reduction we have instituted two changes in the abstracting arrangements. We have reduced the maximum length of abstracts from 300 to 100 words; an interesting byproduct has been what seems to us an apparent improvement in quality and accuracy. We have also made most abstracting agreements selective, generally restricted to about one-half the articles in any annual output of a journal.

Article Classification

The application of the *AEA* classification system involved formulation of key and marginal concepts in each subject class. It also required the training and supervision of the requisite part-time personnel, generally graduate students. The decision to use part-time personnel was motivated by an attempt to hold costs down and to afford training to graduate students by intensive exposure to current literature.

Fourth Digit

We have also completed, insofar as one ever completes this sort of thing, the mandate to develop a fourth digit for the new *AEA-JEL* classification scheme and thereby increased the number of "pigeon-holes" from slightly under a hundred to somewhat more than three hundred. The fourth-digit material will be available as we publish the annual *Indexes*. Mrs. Truus Koopmans (Yale) and A. Maeshiro and J. Wells (both of the University of Pittsburgh) as well as the 1970 cadre of classifiers (Leigh Boske,

---

[1] To some extent the increase during the early years represents rationalization of procedures—making sure there were complete volumes for the journals covered; maintaining sequence order in journals; printing Tables of Contents and abstracts at the same time. The establishment of systematic listing thus delayed the inclusion of certain journals and probably led to abnormally low numbers processed in the first two years.

Thomas Mason, Manharlal Vyas, Andre Lumbroso, and Donald DePamphilis) were helpful in this effort.

Annual Indexes

As I shall note below, it has taken us somewhat longer to work out the publication of the annual *Indexes* than we had anticipated; but the 1970 volume is presently in the hands of the printer. It will be followed by the 1971, the 1972, and the 1969 volumes. Preparation of volumes has turned out to be far from the marginal job that I had once anticipated. Our task was probably complicated by a decision to introduce computerization of articles listings for immediate use in *JEL* and subsequent use in the *Indexes*. In any event, the additional work included the selection and classification of articles in volumes of collected essays and certain United States government documents. For 1970, the articles included from books represented an addition of about 40 percent of articles already classified for journals.

As I mentioned, we have indexed over 200 journals for each of the six years we have published the *Journal*. We have also indexed material in 200 books of collected essays, plus selected articles in several hundred documents for 1969, 1970, 1971, and 1972. Our proposal is to continue the indexing of books of collected essays for 1973 and 1974, but not to include the selected government documents. It turns out that the cost of each government document entry is very high (a multiple of ten to twenty times the cost of the other essays), and budget constraint identifies that as one of the leading candidates for cost cutting. We have prepared a corrected tape of journal articles, collected essays, and documents for 1970 and proofread that print-out; it is now at the printer. We have proofread the computer print-outs of the journal data for 1971 and 1972 and prepared inputting sheets of the books and documents for the Kingsport Press computer. We are on the threshold of preparing inputting sheets of the complete 1969 file; it will then be ready to send to Kingsport for inputting on the computer. The 1973 print-out of journal material is awaiting proofreading. Our hope is to take advantage of this momentum and bring the annual *Indexes* up to publication date about eighteen months after the end of the title year; for example, the 1974 volume should be ready by July of 1976. This apparently long delay is not completely a product of our making. A great many journals dated 1974 will not be published and in our hands until the autumn of 1975 (such are the delays associated with modern printing, to say nothing of modern postal service). If they are in our hands by September of 1975, we can assume that they will be classified, checked, and proofread by the end of 1975. This kind of timing means that the whole manuscript will be ready to go to the printer in the early months of 1976. I believe it is not unlikely that the printer should be allowed about six months to produce the finished product. That is how July of 1976 seems to be a reasonable target date.

What has taken so long in the preparation of these volumes has been computerizing of the data base. This data base, in the form originally suggested to us by Richard Ruggles, has been on various computers since the summer of 1971. Originally we used the University of Pittsburgh computer, but our base had to be transferred to Yale University when the University of Pittsburgh shifted from an *IBM* system to another computer system with a different computer language. We continued to use the Yale University computer, through the kindly intervention of and generous subvention by the National Bureau of Economic Research (this is a splendid opportunity to thank John R. Meyer and Orin Hansen, as well as to take notice of the aid we were given from a grant to the National Bureau of Economic Research by the International Business Machine Corporation). About a year ago we began the transfer of our data processing from the National Bureau of Economic Research facilities on the Yale University computer to Kingsport Press in Kingsport, Tennessee. This final transfer, which we assumed would not be too difficult, has proceeded with dispatch. Of course, some adjustments have had to be made for differences in software as well as compatibility of programs, but, all in all, we have made the transition with reasonably little pain.

Computerizing the data base, which in effect makes it possible to access data entries by journal (issue), by author, by any one of several subject matter codes (including geographical descriptors), or by year of publication, requires far more proofreading than we had even anticipated. My staff often speculates, when we see obvious errors because of letter substitution or items left out, whether "numbers crunchers" have the same troubles that people who print upper and lower case words have. In any event, computerizing of the data base was a "noble experiment"; unlike previous noble experiments, we have not turned our back on the experience, but we are somewhat the wiser about the costs involved.

Report on 1974

Table 1—Quantitative Analysis of Contents (1969–74) again illustrates our product. Members will note that we seem to have published a slightly smaller journal than we published in 1973. In reality, it actually contains more words because we shifted for 1974 to a more compact typeface, Times Roman. Several people have noted a difficulty in reading this compact typeface. We are planning to revert to a typeface comparable to the one we used prior to 1974, but this shift, it was decided,

would take place only with the next issue (March 1975).

As I noted above, we printed only three survey articles this year. They covered, however, 102 pages. We printed five essays in subfields which covered ninety-nine pages, but one of these essays on a subfield was a substitution for a survey article. We printed only one review article this year. There were no articles about economic literature, however. We had a record number of communications, largely mop-up operations and comments about previous articles. We annotated about the same number of books which we have done for the past few years. We reviewed 168 books; the reviews were longer and, we hope, more analytical. As I noted above, we indexed fewer journals' issues than in the previous year, but still a high number. We actually indexed a larger number of articles (7,360) than we had done in previous years. One decision which I took early in the year was to "catch up" and thus to increase the number of article listings in the early months of the 1974 printing contract because costs of printing this material was likely to go up as the year progressed. You will note that we have fewer pages devoted to a subject index of journal articles, but that again is a phenomenon associated with a more compact typeface. We had fewer abstracts of articles, reflecting a decision made by the Board of Editors two years ago to request editors of journals with which we had abstracting agreements to submit abstracts for only a portion of the articles they had printed.

My annual report in December 1973 included an explanation of the processes we use to train annotators and article classifiers. The Associate Editor supervises these processes as well as reviewing the articles, book reviews, and annotations with me for subject matter consistency. The Assistant Editor, Drucilla Ekwurzel, is an economist and, besides preparing the manuscript for the printer and seeing the proofs through the various stages, is able to help us with the subject matter monitoring.

The Chancellor and the Dean of the Faculty of Arts and Sciences of the University of Pittsburgh have helped the American Economic Association by the assignment of two to three teaching assistants to the *Journal* plus the allocation of space and equipment.

I have included in Table 2 brief reference to the costs of putting out the *Journal of Economic Literature*. It is appropriate that the cost problem be basically discussed most thoroughly with the Executive Committee, since it is for that reason, amongst others, that the responsibility for the administration of the Association is vested in

TABLE 2—EXPENDITURES 1969 THROUGH 1974[a]

the Executive Committee. We have pursued what we believe are cost-effective policies. We anticipate an increase in the printing cost of putting out the *Journal*, particularly because of the rise of paper cost. However, the fact is that our costs have not risen in proportion to the rise of retail prices. Part of the reason for that moderation is a reluctance to raise the basic cost of hourly help. I have asked the Executive Committee to permit me to raise this price because the *Journal* is no longer competitive with other projects around the University of Pittsburgh. Thus, I am asking for an increase in our budget for 1975; however, it, too, is not commensurate with the rise in the cost of living. Part of this latter example of restraint can be explained by increased productivity of our staff (the turnover has been very light), but part of it also is explained by a posture of studied administrative cynicism.

Table 3 refers to the technical difficulty of material in the *Journal of Economic Literature*. Again, we have tried to maintain a viable balance between material that will interest subject matter specialists and material that will be of interest to all the members of the Association. The problem is not only one of technical jargon; it is also a problem of subject matter and analytical method. I am grateful to the number of members who have written in with suggestions for new articles or with comments about the articles we have printed (it is always gratifying to receive a large number of appreciative letters—many come, but we also get some letters suggesting that articles are technically too sophisticated or, in some instances, erroneous choices).

TABLE 3—CLASSIFICATION BY TECHNICAL DIFFICULTY

	Surveys	Creative Curmudgeon Articles	Others[a]	Total
Most Difficult	7	7	3	17
Some Difficulty	10	11	12	33

Totals	19	21	39	79

[a] Review articles or books and general essays on all literature; excludes very short communications.

Table 4 shows the distribution of material by subject matter area. It extends only to the commissioned material, but I believe that a quick glance at the distribution probably mirrors the preferred reading area of most of the members of the Association. If not, do let me know.

The 1975 Issue

In the 1975 volume we anticipate having four survey articles. One will be a survey of the literature on research and development; another will be a survey of the studies on the impact of increased women's participation on the economy; a third will be a survey on recent work in government regulation in industry; and the fourth is most likely to be a survey on the empirical work done on economic migration.

We have under consideration quite a few interpretive essays. Most of these articles are commissioned; indeed, it is probably fair to state that all articles are sooner or later "commissioned" insofar as everything goes through the rather tedious and careful refereeing process with the outcome invariably requiring considerable refocusing and/or rewriting. I have used a great many members of the Association to assist me in this refereeing process. Perhaps no one is used more frequently than the members of my Board of Editors. Three are finishing their terms of service at the end of this calendar year. They are Abram Bergson (Harvard University), Harry T. Oshima (Rockefeller Foundation/University of the Philippines), and Arnold Zellner (University of Chicago). Each has been a gracious and generous

colleague. I am personally most grateful to them and take this opportunity to note their service to the members of the Association. The foregoing is not to minimize the contributions made by the other members of the Board of Editors; fortunately for me, they serve at least another year. These include Marcus Alexis, (Northwestern University), Martin Bronfenbrenner (Duke University), Anne P. Carter (Brandeis University), Anne O. Krueger (University of Minnesota), Tibor Scitovsky (Stanford University), and William S. Vickrey (Columbia University). I am asking the Executive Committee to approve replacements for those who have left the Board, but until such action has been taken by the Executive Committee it is premature to list those names.

Finally, I want to thank the following individuals, plus four anonymous parties, for specific acts of assistance to me during this calendar year:

MARK PERLMAN, *Managing Editor*

REPORT OF THE DIRECTOR
JOB OPENINGS FOR ECONOMISTS

Four years ago at these meetings, Allan M. Cartter projected a substantial oversupply of new Ph.D.'s during the 1970's and urged the Association to study measures that might minimize the painful readjustments necessary to overcome a near-permanent disequilibrium in the market (Cartter, p. 305–10). Generalized gloom and dissatisfaction prevailed about both the state of the market and its workings. As a result, in 1971 the Association adopted a resolution calling for a radical improvement of hiring practices in the profession and open listing of all employment opportunities.[1] Pursuant to that resolution, the Committee on Hiring Practices (F. Ray Marshall, Chairperson) was established. At last year's annual meeting, the Executive Committee approved the Committee's recommendation of a bimonthly publication for open listing of vacancies and resolved that "all members of the *AEA* have a professional obligation to list their openings with the Association."[2]

Two issues of *Job Openings for Economists* (*JOE*) have been published. The October issue contained 249 openings, and the December one contained 494. Six hundred thirty-one (631) different jobs have been listed, of which about 85 percent are academic. The fields of specialization most in demand were general economic theory, econometrics, urban economics,

[a] Estimated.

business finance, and public finance (see Tables 1 and 2). Each vacancy may be classified by more than one field of specialization. Hence, the number of field citations exceeds the number of job openings.

Participation by the "prestige" departments has been good. Of the top ten ranked schools in the Roose-Andersen report, eight have listed vacancies; of the next nine, six listed; of the next ten, seven; and of the last sixteen, eleven—for a total of 32 out of 45 (over 70 percent). Of the sixty-two departments in the Chairman's Group, forty have listed openings. If other departments had participated to this extent, marginal costs would have exceeded marginal revenue by a goodly sum. Printing and mailing costs alone (excluding salaries and overhead) were $.47 for the October issue and $.86 for the December one (see Table 3). Salary, overhead, general supplies, and other costs of *JOE* are not allocated from the general budget of the Association. However, the director estimates that total costs exceeded total revenue by about $12,000 during 1974. We began with 1,858 subscribers and now have 2,275.

No listing will be accepted for *JOE* containing material which violates federal civil rights laws. Institutions under censure by the *AAUP* may list vacancies, but the censureship will be noted. Listing a vacancy presumes that the position will not be filled until applicants have had a reasonable amount of time to respond (i.e., thirty days).

Listing is simple, fulfills a professional obligation to the Association, increases information available in the market, and may indicate good faith to other interested parties. All for no charge to the employer.

C. ELTON HINSHAW, *Director*

REPORT OF THE COMMITTEE ON THE STATUS OF WOMEN IN THE ECONOMICS PROFESSION

During the past year the Committee has improved the operation of the market for economists, added to the information about the economics profession, and increased the effective supply of women economists.

The unique nature of this Committee should be noted. It is a "working committee," which this year has produced better information flow in the current job market, collected new, needed data, produced research results, planned and conducted a session at the *AEA* annual meeting, is in the process of producing a national research conference on occupational segregation, and has offered encouragement and support to women economists who have registered with us. The number of registered women economists is close to 1,400.

The need for this Committee, unfortunately, is far from being met. In recognition of this fact and the productiveness of the Committee, the Executive Committee of *AEA* in March 1974 changed the status of this Committee from that of an *ad hoc* one to a standing committee. On behalf of our Committee members, I wish to thank the Executive Committee for this expression of appreciation of our work and of faith in our continued performance.

I also want to thank the individual members of our Committee who have so diligently carried out the mandate of this Association. The Committee deliberately was made larger than some *AEA* committees and consists of ten members. It was designed carefully to have diversity by geographic location, age, sex, stage of professional development, and type of home-base institutions, including business, government, and academic.

On behalf of the total Association, I also wish to thank the Ford Foundation for its two grants to the *AEA* over the past three years which have enabled the rapid growth of this Committee's work. With this support, the Committee has been able to undertake important projects in line with its charge from the *AEA*. The nature of the experiment that the Ford Foundation financed was that this was to be part of the regular *AEA* structure; it was to pursue the goals set by *AEA* for the benefit of the total Association; and, if the experiment worked, the Committee and its activities would be continued by *AEA*. As we come to the end of the three-year start-up period, it is appropriate to recognize that this goal has been met and to recognize again the tremendous help that the Ford Foundation has been in making this quantum leap possible.

More specifically, the work of the Committee on the Status of Women in the Economics Profession (*CSWEP*) during this past year has included the following:

1. Four *CSWEP Newsletters* have been written during 1974 and sent to nearly 1,400 women economists. The newsletter is one way the Committee improves the working of the market by listing job openings for economists submitted by prospective employers. This activity fills a need most appreciated by agency and department heads, as our voluminous correspondence shows. The *CSWEP Newsletter* also lists requests for articles, conference and program plans and participants, grant and fellowship opportunities, and notices of regional activities of women economists. It is also a mechanism by which the Committee can ask the reader for help in various *AEA* projects. The newsletter clearly has helped to widen the informal network

and to support our women colleagues who often have felt isolated in our profession.

2. The roster of women economists developed and computerized by this Committee has been maintained this year and used as the basis for mailing the *CSWEP Newsletter*. It just recently has been updated by sending to all persons listed copies of the material they had previously supplied us and asking for the most recent information on their area of specialization, highest degree in economics, grade or rank, and address. The roster has been used to provide prospective employers with a list of women economists who meet specified criteria such as field, degree, and rank, although it is not known whether they are currently in the job market. (Whether they are or not may well depend on the opportunity.) The prospective employer may write to these economists, ask them to supply career data, and then follow up with interviews if desired. On an interim basis this service is currently being provided for a fee to help defray costs.

A special list of all women economists from the new *AEA Directory of Members* is in process of being run and will be used to add any new names to the roster list. Based on survey returns, the Committee feels that the number of women who have joined *AEA* has increased, directly or indirectly, because of Committee activity.

3. For the previous two years, the survey of academic economists was conducted by the Committee, and the survey results have been widely used. This year, on recommendation of this Committee, the collection of such data was transferred to the Nashville office of *AEA* and combined with the requests for other information from academic departments of economics into the Universal Academic Questionnaire. We participated actively in the development of the new survey and have continued as before to analyze the data related to the supply and demand for women economists. The preliminary results from this survey are presented below. Subsequent work will link these data to the previous data so as to begin to examine change, if any, over the three-year period of the life of this Committee.

4. A special survey of women and men economists in 1974–75 and their work histories is one of our major activities this year. The preliminary results from 710 women respondents and the first returns from a matched sample of male economists have been prepared. These results served as the basis for three research papers presented and discussed at the Annual Meeting session planned and conducted by the Committee. The male sample is still being developed, based on a random sample selected from the *Directory* to match the women respondents.

5. A national, working research conference on Occupational Segregation to be held in May 1975 is being sponsored and organized by this Committee. The conference is being held at the Center for Research on Women in Higher Education and the Professions at Wellesley College and is being financed by a grant from the Carnegie Foundation. Development and execution of this commitment will continue to involve much of our time. Publication plans are now being considered.

6. On-going efforts of the Committee this year have included the encouragement of the commissioning of a forthcoming survey article for the *Journal of Economic Literature* on the economic status of women, informal cooperation with similar women's groups of other professional associations, maintaining liaison with the Federation of Organizations for Professional Women, consultation with individual women economists or department chairpersons who have been concerned about particular cases of possible sex discrimination, answering requests, and urging program chairpersons of regional eco-

nomic associations and journal editors to appoint women to policy positions. Groups of women economists have been encouraged to meet together locally, and often informally, on an on-going basis. Efforts this year particularly have been made to increase the known supply of women economists in business and government.

Women in Academic Departments of Economics, 1974–75

Because no one knew how many women economists existed in academe or how many were currently being trained, this Committee for the last two years surveyed the academic departments of economics and agricultural economics. As noted above, this year similar data were collected under the direction of C. Elton Hinshaw by *AEA* in an expanded survey using the 1974–75 Universal Academic Questionnaire. The preliminary data that relate to women from the 1974–75 questionnaires returned to Nashville so far this year are summarized below. Only a few comparisons of overall totals from the three surveys are made; the data presented are not directly comparable because many departments did not provide data in all three years.[1] For example, last year's data related to 57 institutions in the *AEA*-designated Chairman's Group and this year's data to 47 in that group. Last year, in all, 414 departments with 4,262 full-time economics faculty members responded, and this year, so far, only 311 economics departments with 3,138 full-time faculty members have sent in their questionnaires.

In 1973–74, women comprised 16 percent of the students awarded degrees in economics at the bachelor's level, 14 percent at the M.A. level, but only 8 percent at the Ph.D. level. (See Table 1.) The proportions of women among senior majors in economics and candidates for M.A.s had not changed from the previous year, but the proportion of women receiving Ph.D.s in economics is considerably lower than the 12 percent reported the last two years for women Ph.D. graduate students.[2] It cannot be said that all four points of this difference represent a downturn in women Ph.D.s but this possible decrease bears watching.

The most common forms of financial aid to doctoral students in economics this year are "tuition and stipend with services required," and "tuition and stipend with no services required." Women Ph.D. students received such aid in proportion to their numbers (Table 2). The next most usual kind of financial aid is "stipend only with services required," and considerably less common, "tuition only with no service required." Disproportionately fewer women received these two forms of aid.

The 1974–75 employment of women who received Ph.D.s in economics in 1973–74 is similar to that of the men Ph.D.s except that more women are employed in academic institutions (68 percent of the women versus 56 percent of the men) and fewer women work in the federal government or are employed outside the United States (Table 3). Hinshaw suggests that the proportion of last year's Ph.D.s and *ABDs* finding employment in academic institutions this year is down considerably from the previous level.

The proportion of undergraduate women majoring in economics in Ph.D.-granting departments is much lower than in departments where the highest degree granted is an M.A. or a B.A. (This was also true last

---

[1] In the fall of 1973, questionnaires were sent to 1,409 departments of economics; in the fall of 1974, they were sent to 1,453 departments. Findings from last year's survey were reported by Carolyn Shaw Bell. Other preliminary findings from the 1974–75 survey have been reported by Hinshaw.

[2] The two previous surveys obtained data on students enrolled rather than degrees granted.

[a] Includes graduate students who have not completed their dissertations, if they entered the labor market seeking full-time employment as economists.

year.) This year the proportion is nearly 12 percent in Ph.D.-granting departments and nearly 20 percent in non-Ph.D.-granting departments. These overall data again suggest that the proportion of women undergraduate majors is positively correlated with the proportion of women faculty. The proportion of women among full-time faculty in tenure-track positions is 3 percent in Ph.D.-granting departments and 6 and 8 percent, respectively, in departments where the highest degree granted is an M.A. or a B.A. (Table 4).

Departments in the Chairman's Group have a low proportion of women among the full-time faculty in tenure-track positions at professor and associate professor levels (1 percent), but they have a much higher proportion of women at instructor and "other" levels (33 percent). The number of full-time faculty in non-tenure-track positions in the Chairman's Group is about the same as the number of part-time faculty members in those depart-

[a] In all departments, fourteen of these positions are tenure-track, seven as professors. All seven of the professors are in departments that are in the Chairman's Group.

[b] In all departments, five of these positions held by women are tenure-track, one at each rank.

ments, each about 8 percent of the total faculty. Women hold 15 and 16 percent of these two types of positions. The non-Ph.D. departments, on the other hand, depend much more on part-time faculty (15 percent of the total faculty) and have a relatively high proportion of women in the part-time positions (nearly 20 percent versus about 2 percent in the full-time but non-tenure-track positions).

The continued existence of all-male economics faculties is of particular interest. Considering full-time faculty, 30 percent of the departments in the Chairman's Group have no women faculty (a similar proportion to that reported last year), 45 percent of the other Ph.D.-granting departments have no women faculty, and nearly 70 percent of the non-Ph.D.-granting departments are all male (Table 5). The proportion of departments with all-male part-time faculty (30 percent) exceeds the proportion with one or more women among the part-time faculty (18 percent).

Overall, the number of full-time economics faculty increased 2 percent from 1973–74 to 1974–75 (Table 6). This was an increase of eighty-six positions for the departments reporting, with thirteen of them being held by women (15 percent). Women represented 8 percent of the full-time faculty released (resignation, retirement, and nonrenewal of contract) and 9 percent of the new hires for full-time faculty positions. Of the overall net changes in full-time faculty, women represented a larger proportion of the increase in departments in the Chairman's Group than in other departments (23 versus 12 percent). This is

[a] Resignation, retirement, and nonrenewal of contracts.

primarily due to the fact that five women represented 18 percent of the net increase at the assistant professor level in the Chairman's Group, but the number of women at that level in the other departments actually decreased. It should be noted that there was a net increase of three women at the associate professor level in the other departments.

Considering part-time faculty for all departments, the new hires of women exceeded the number released by nineteen and was primarily at the "other" rank. Most of this increase in part-time employment for women took place in departments that are not in the Chairman's Group.

The women employed as new hires for a given department this year tended to come less from other faculties, business, or government than did men, and to have come more from graduate students (Table 7). This is related to the fact discussed above that much of the increase in women hired has been for part-time jobs at lower faculty ranks. Among the women released

last year by the reporting departments, none had retired (compared with 7 percent retirees among the released men). Relatively fewer women than men who were released went to business or industry or to positions outside the United States, but relatively more women went to other faculty positions. This pattern is similar to that reported above for types of employment for women with new Ph.D.s.

The economics departments reporting were asked this year to rank women full-time faculty by whether their salaries were above or below the departmental median for the particular rank and whether their length of service in that rank was above or below the median time at that rank for departmental faculty. Such estimates ignore how much the woman's salary is above or below the median. In these days when sex discrimination in pay is illegal, there undoubtedly is reluctance to report lower salaries for women. Nevertheless, the data reported reflect the situation as seen by department chairpersons or their reporting agents. For all departments, 36 percent of the women faculty were reported to have salaries more than $250 below the median (Table 8). When time in rank is also considered, 10 percent were below the median salary even though they were at or above the median time in rank. At the other end of the distribution, 20 percent of the women had salaries above the median with time in rank at or below the median time.

Women obtained 5 percent of all promotions (twelve of the 232), whereas they comprised 6 percent of all full-time faculty (Table 9). The promotions reported for women included one to professor and one to associate professor in the Chairman's Group (two out of sixty-nine, or nearly 3 percent), one to associate profes-

sor in the other Ph.D.-granting departments, and six promotions in departments where a B.A. is the highest degree granted.

Effective affirmative action at the department level is probably more a matter of action by men of good will and sensitivity who try to act in good faith to open opportunities to women economists and to change traditional attitudes so as to offer better educational opportunities for women than it is a matter of coerced action. Undeniably, however, the threat of coercion has increased men's awareness. In some educational institutions, Affirmative Action (*AA*) offices at the central administrative level have been effective in increasing awareness of legal and moral responsibilities and in facilitating implementation of *AA* plans. At the department level, perception of the effectiveness of *AA* offices may well be a combination of the particular experiences of the economics department and a projection of the values of the department chairman or his agent who answers the questionnaire. In all, 71 percent of the departments were in institutions with *AA* offices (Table 10). Of these, 80 percent had been in some type of contact with the office. Of these, 55 percent found the *AA* office useful, 35 percent found it "not at all useful," and 10 percent found it a "damned nuisance." Among the Chairman's Group, all departments were in institutions with *AA* offices, and 91 percent had been in contact. Of these 35 percent found the *AA* office to be useful, 42 percent "not at all useful," and 23 percent, a "damned nuisance." Resentment of *AA* appears to be greater among department chairpersons in the Chairman's Group than in other departments of economics.

It is not often that authors of an article have a chance to quantify the proportion

of department chairpersons who have read a given article. In the December 1973 issue of the *American Economic Review*, Kenneth E. Boulding and Barbara B. Reagan on behalf of this Committee wrote an article, "Combatting Role Prejudice and Sex Discrimination." (Informally among Committee members this article was referred to as guidelines for good guys.) Over 40 percent of all department chairpersons and nearly 50 percent of the Chairman's Group reported that they had read this article, and 68 and 64 percent, respectively, said that they had used suggestions of the article.

BARBARA B. REAGAN, *Chairperson*

SUMMER PROGRAM IN ECONOMICS FOR MINORITY STUDENTS

The Summer Program in Economics for Minority Students was originally conceived in 1969 in discussions between the Caucus of Black Economists and the Executive Committee of the American Economic Association. Members of the Caucus were distressed about the small numbers of minorities in the economics profession and concluded that this shortage could only be remedied by an intensive program of solicitation and education of young minority men and women who had not completed their undergraduate education and who showed signs of promise as evidenced by their work in economics and related subjects. The Caucus and the American Economic Association's Executive Committee agreed that a committee should be formed to investigate the matter in depth. Such a committee was formed and began functioning in January in 1970. The Committee conducted an in-depth survey of minority holders of advanced degrees in economics and of minority students studying economics on the undergraduate level in the major black institutions; it also surveyed the curriculum of these institutions. After the survey, it was even more clear that if minority students were to have any prospects of being admitted into and performing at a high level in the most competitive programs in economics, many of them would require additional work in economics theory and quantitative methods.

In the Summer of 1971 members of the American Economic Association Committee on Minorities and Members of the Caucus of Black Economists met in Boston under the chairmanship of Robert Dorfman of Harvard University to discuss plans for establishing one or two summer institute programs of intensive work in economic theory and quantitative methods for minority students. Because of difficulties in making adequate financial arrangements and the unavailability of a suitable host institution, these sessions did not culminate in a summer program. A similar effort in 1972 was also aborted. Thus, three opportunities (1970, 1971, 1972) for minority students to obtain suitable backgrounds to enter the mainstream of economics education at the graduate level eluded the efforts of the American Economic Association's committee. A similar fate was to befall a proposed institute in the summer of 1973.

In 1974, Marcus Alexis, a charter member of the Caucus of Black Economists and a member of the American Economic Association Committee on Minorities who teaches at Northwestern University, took it upon himself to move the project forward, fearing that a fifth year might pass without a summer program for minority students.

In January 1974 he inquired of Richard Holton, Dean of the Graduate School of Business at the University of California, Berkeley, if the Berkeley campus would be willing to host a Summer Program for Minority Students, sponsored by the American Economic Association and funded by outside agencies. Receiving an affirmative reply, he communicated the information to Robert Dorfman, chairman of the committee. Dorfman was enthusiastic and at the March meeting of the Executive Committee of the American Economic Association formal approval was given to seek financing for the Summer Program and to solicit applications from minority students.

The Alfred P. Sloan Foundation con-

TABLE 1—BUDGET ALLOCATION FOR SUMMER PROGRAM IN ECONOMICS FOR MINORITY STUDENTS, 1974

Students	
Stipend—22 @ $200	$ 4,400.00
Room and Board—22 @ $500	11,000.00
Transportation	8,204.79
Faculty	
Salaries (includes teaching assistants)	18,403.08
Transportation	2,589.20
Teaching Materials	6,024.46
Administration and Facilities	7,372.83
	$57,994.36

tributed $20,000 towards a proposed Summer Program. Inquiries made at the Ford Foundation produced encouraging responses. The Ford Foundation later made a grant for the Summer Program of $25,000. Through the efforts of several members of the Executive Committee of the American Economic Association, additional funds were received from other interested parties.

Because of the late start (March 1974), it was necessary to launch an intensive program campaign immediately to interest students, to assemble a staff, and to make administrative arrangements with the Berkeley administration. After three months of frenetic activity, the Summer Program for Minority Students became a reality.

Recruitment

On the basis of letters of recommendation and student transcripts, thirty students were offered positions in the Summer Program even though funds had been secured in amounts to finance only twenty-five. In the end, twenty-five students did accept the invitation to be members of the Summer Program. But by the time the program began on June 20, three of the students had to withdraw. Twenty of the students were black, one was of Latin extraction, and one was a mixture of black and Latin. The students came from a wide variety of schools and were well represented geographically. Twelve of the twenty-two students came from predominantly black colleges. Of these, five were from the Atlanta University complex, two from Benedict College (South Carolina), and one each from Fisk University (Tennessee), Talladega College (Alabama), Tougalloo College (Mississippi), Bishop College (Texas), and Savannah State (Georgia). The remaining ten students came from Cornell University (New York), Oklahoma State University, City College of New York, University of Massachusetts (Boston), University of Pennsylvania, LaSalle College (Pennsylvania), Oakland University (Michigan), Northeastern Illinois University, Mills College (California), and Hayward State College (California).

No attempt was made to predict the performance of the students in the program. With one exception, all of the students had cumulative grade point averages of 3.0 or better. Each student was strongly recommended by at least one faculty member from his or her institution. The small number of students did not permit any formal experiment to ascertain whether students from one type of college would perform best. The final results showed, however, that students from predominantly black institutions performed as well as those from majority white schools. This limited evidence suggests a large reservoir of untapped talent in these schools.

Curriculum

The curriculum in the Summer Program consisted of microeconomics, macroeconomics, quantitative methods, and expository writing. In microeconomics students were expected to master material at the level of Edwin Mansfield's *Microeconomics* text, and William J. Baumol's *Economic Theory and Operations Analysis.* In macroeconomics the primary text was Thomas F. Dernburg and Duncan M. McDougall, *Macroeconomics.* The text in quantitative methods was Alpha Chiang's *Fundamental Methods of Mathematical Economics.* The instruction was evenly divided between microeconomics, macroeconomics, and quantitative methods. Students spent a minimum of fifteen hours in class each week. There were five hours of lecture per week in each of the three subjects and often supplementary sessions. In addition there were ten hours of laboratory work in which students could receive assistance in troublesome assignments from three teaching assistants hired for the program. Microeconomics was taught by Marcus Alexis of Northwestern; macro by Terry Turner of the University of California, Berkeley; and quantitative methods by Glenn Loury, a third-year graduate student at Massachusetts Institute of Technology. The three teaching assistants provided a total of sixty hours per week. They were carefully selected by Turner and they proved to be outstanding. Each of them was a fourth-year graduate student in applied economics at the University of California, Berkeley.

In addition to the formal lectures and laboratory sessions, there were three simulated economic games developed in the Behavioral Science Laboratory of the Center for Research in Management Science at the University of California, Berkeley. Leonard Doyle of the University of California, Berkeley faculty assisted in the briefing of the students and the write-ups explaining the purpose of the economic games. The simulation was an immense success, both because the students enjoyed them and because they did so well in the exercises. Another factor in the success in the simulations was that they gave the students an opportunity to apply the concepts and tools they had acquired in the more formal classroom sessions and in homework. In future programs, more of an attempt should be made to provide students with opportunities to apply their knowledge to problems of policy and solutions to economic problems faced by professional economists.

Seminars and Counseling

The Summer Program was fortunate also in having a very successful set of seminar speakers. Charles E. Wilson, Vice-Chancellor of the University of California, Los Angeles, was the first visitor and spoke to the students of opportunities in economics for minority students and of the use of economics in solving administrative problems in complex organizations. Durand Bell of the University of California, Irvine, spoke on the "Minimum Wage Reconsidered." Donald J. Harris, University of Wisconsin, Madison, spoke on "A Critique of Neoclassical Growth Theory." Richard Sutch, professor of economics at the University of California, Berkeley, gave an in-depth analysis of *Time on the Cross*, a volume which the students had read in preparation for the seminar. Finally, Robert Aaron Gordon of the economics department at the University of California, Berkeley, discussed prospects for careers in economics and presided at the closing session of the Summer Program.

In addition to the formal classwork, seminars, laboratory sessions, simulations, and homework assignments, a very important aspect of the Summer Program was the counseling that students received. Most of the students knew little about the offerings of the various graduate programs in economics and of the relevant standings of various departments. Very early in the program an effort was made to prepare students for the demands that would be placed upon them by the better economics departments. The schedule of the Summer Program was intentionally made very intense in an attempt to simulate conditions in graduate schools. This afforded an opportunity for those students who would be discouraged at such a work load to reflect on whether they were willing to make the sacrifice in time and effort required for success in the more competitive economics departments, and for the students and the faculty to evaluate their potential as future graduate students in economics. The counseling consisted of formal and informal discussions of graduate programs available and the emphasis in these programs. The counseling included such routine matters as how to solicit information from graduate schools, financial assistance, completion of applications, and candid appraisals of students' chances for admission and success in schools in which they showed interest.

Postprogram activity has included contacting schools on behalf of the students, writing letters of recommendation, and advising students on the appropriate courses they should take in their fourth year of college. The latter was extremely important because most of the students were entering their senior year, many with the need of additional course work in mathematics, statistics, and courses in economic theory and analysis. Letters from the students since the program indicate that this has been well received.

MARCUS ALEXIS

REPORT OF COMMITTEE ON ECONOMIC EDUCATION

In 1974, this Committee continued to develop the program laid out in its 1972 agenda for improving the teaching of economics (published in the *American Economic Review* in May 1973). We wish to call the attention of the profession especially to three developments.

(1) The project outlined in the 1972 agenda to help university economics departments provide improved training in teaching for new Ph.D.s has been broadened and extended to five universities. The goal of the program is to help potential teachers on both techniques of teaching and the subject matter of basic economic courses which they will probably be asked to teach; greater details are provided in the May 1973 issue of the *Review*.

During 1973–74, the Universities of Minnesota and Wisconsin used the new program with substantial success. On the basis of this experience, further improvements have been made in both the written and video tape materials designed to help potential teachers, and they are being used in four additional schools in 1974–75—Florida State, Indiana, Nebraska, and Purdue Universities. Current plans for the program involve extending the experiment to at least five more schools over the two years ahead.

The Committee hopes that these experiences, teaching materials, and information on teaching techniques for new teachers may be useful to a wide variety of universities training future teachers. Further information can be obtained by writing to Dr. Arthur Welsh, Joint Council on Economic Education, 1212 Avenue of the Americas, New York, New York 10036.

(2) The first of the new *Readings* series, designed to help teachers at smaller institutions keep up-to-date on central areas of economic theory and policy, has appeared under the title *Recent Advances in Economics*. The series, to be published by Richard Irwin, Inc., is under the editorship of Rendigs Fels and John Siegfried of Vanderbilt University and the general policy guidance of this Committee. The readings have been selected especially to help teachers of economics at community and junior colleges and at other less-known colleges and universities where faculty members often find it difficult to keep up with new theory and policy developments and to do an adequate job of teaching a variety of courses. Each annual volume will include a series of articles, reprinted from economic journals and other sources, aimed at pulling together at one place materials that may be especially useful.

(3) At the 1974 meetings of the Association in San Francisco, this Committee sponsored an exhibit on innovations in the teaching of undergraduate economics. The Committee invited teachers who have been experimenting with new techniques and technological developments in the teaching of economics to exhibit their experiments in a "hands-on" mode so that economists visiting the convention could see for themselves how the new developments work. The primary goal was to make information on these new developments available as widely as possible throughout the profession.

The exhibits, together with the individuals from whom further information can be obtained on each, are indicated below:

1. *Macro Simulation Models for Use with Time-Sharing Computers.* A simple model of the economy is put on the com-

puter, and students are able to change the tax rate, government expenditures, and the money stock in attempts to stabilize a moderately complex economy. Different welfare functions are given to students to be maximized. (Richard Attiyeh, University of California, San Diego, and Keith Lumsden, Stanford University.)

2. *Teaching Information Processing System* (*TIPS*). An extensive review of basic economics has been programmed on a computer so that students can review for themselves at their own pace how well they are learning the material contained in traditional economics texts. In effect, the computer substitutes for a combination workbook and teaching assistant. (Allen Kelley, Duke University.)

3. *Study Management System* (*PLATO*). This system is similar to *TIPS* in that it permits students to study at their own pace the subject matter of a standard elementary course. It includes individual study and review material. Students, using the computer, answer a series of examination questions and are either told to go on if they perform satisfactorily or helped to review individually if they need further assistance. (Don Paden and Bruce Delgaard, University of Illinois.)

4. *Computer-Aided Instruction Modules in Intermediate Macroeconomics.* This is a series of modules in teaching intermediate macroeconomics, stressing problems and situations involving computations—for example, accelerator-multiplier models, monetary models, and the like. They are designed for teachers who want to save class time for other activities. (James Weatherby and James Peach, University of Texas at Austin.)

5. *Open University Economics Courses.* In the United Kingdom, open university courses have been offered in economics as well as other fields. TV instruction and cassettes are used for audio-visual teaching, plus newly developed reading materials. While the materials are designed for United Kingdom students, a number of the modules can be readily adapted for American use at the elementary level. (Leslie Wagner and Anthony Mellor, The Open University, Walton Hall, Walton, Bletchley, Buckinghamshire, London, England.)

6. *Teacher Training Program for New Ph.D.s.* Materials are now available, including extensive written suggestions and video tape materials, on the new program to aid Ph.D.s preparing for college and university teaching posts, described in the first paragraph above. Most of these materials have been developed by the group responsible for the program; some are specifically drawn from course experiments at the University of Minnesota, where video tapes have been used with especially good effect. (For basic materials, write Dr. Arthur Welsh, Joint Council on Economic Education, 1212 Avenue of the Americas, New York, New York 10036; additional information can be obtained from William Becker and Michael Salemi, University of Minnesota, and Phillip Saunders, University of Indiana.)

7. *Interdisciplinary Introductions to Economics.* Combined programmed learning books and video tape "grabbers" to get students involved in material being taught at different stages of an elementary course have been developed. These video tape introductions may be useful at other universities. (John Kuhlman, University of Missouri at Columbia.)

8. *Video Cassette Modules for Basic Economics.* Video tape modules are being developed for students in evening classes, especially adult students attending school on a part-time basis. Units are at an elementary level. (Douglas Poe, Illinois State University.)

This experimental exhibit was made possible by a generous grant from the Calvin Kazanjian Economics Foundation, which has for many years provided prizes for outstanding economics teachers at grade school, high school, and college levels, and which is prepared to provide copies of the winning teaching projects at different levels to those who write for them. The address is 251 Danbury Road, P.O. Box 452, Wilton, Connecticut 06897. The Committee also is especially indebted to Keith Lumsden of Stanford who undertook the responsibility of arranging the exhibit and seeing to its implementation.

G. L. BACH, *Chairperson*

REPORT OF THE ECONOMICS INSTITUTE POLICY AND ADVISORY BOARD

Each year since its inception in 1958 the Economics Institute has provided an intensive summer program of academic training and orientation for international students who are preparing to begin graduate study in the United States in economics and related disciplines, including business and agricultural economics. Continuing under the dedicated directorship of Wyn Owen, the Institute enrolled a record student body of 222, representing fifty-three foreign countries, in 1974.

Each summer the Institute offers intensive academic course work in economic theory, statistical methods, mathematics, business, and English, supplemented by special lectures, seminars, and field trips. By virtue of its increased size, the Institute was able to respond to more diverse student needs in recent years by providing an eleven and a half weeks extended session, a nine and a half weeks main session, and five and a half weeks short session. In 1974, the Institute also sponsored three associated projects: a conference in which doctoral candidate foreign students could discuss their research with each other and with current Institute students; the third edition of *Guide to Graduate Study in Economics and Agricultural Economics in U.S.A. and Canada;* and a research project on academic performance of Institute alumni.

The Institute was initiated with the aid of a grant from the Ford Foundation. Ford continues to support the program by providing a revolving guaranty fund and with a limited amount of fellowship aid. The program is, however, essentially self-supporting from tuition and fee charges substantially paid by a total of forty-eight sponsoring agencies, twenty-eight of them foreign.

The Institute now has a total of 1,654 alumni, many of whom are in important academic, government, and business posts throughout the world. The success of its alumni in their academic programs and their subsequent careers attests to the value of the Economics Institute. It is anticipated that the Institute will have an important role to play in international education for the foreseeable future.

The current members of the Board are Irma Adelman, Walter P. Falcon, Edwin S. Mills, Daniel Schydlowsky, Arnold Harberger, and Richard Holton.

EDWIN S. MILLS, *Chairperson*

REPORT OF REPRESENTATIVE TO THE INTERNATIONAL ECONOMIC ASSOCIATION

During the calendar year 1974, the International Economic Association held a conference in Italy, a world congress in Hungary, a workshop in Turkey, and an East-West meeting in Switzerland.

The conference in Turin, Italy, April 1 to 6, was on "The Economics of Public Services." It was prepared by a program committee chaired by Martin Feldstein (United States) with Anthony Atkinson (United Kingdom), Francesco Forte (Italy), Eugeny Gromov (*USSR*), Serge-Christophe Kolm (France), and Jean Paelinck (Netherlands) as members. Besides Feldstein, nine Americans participated: Henry Aaron, David Bradford, Harold Hochman, Robert Inman, Alvin Klevorick, Fritz Machlup, Mark Pauly, Joseph Stiglitz, and William Vickrey.

The World Congress in Budapest, Hungary, was held from August 19 to 24 on "Economic Integration: Worldwide, Regional, Sectoral." The Program Committee, chaired by Fritz Machlup, included: Bela Balassa (United States), Raymond Barre (France), Oleg Bogomolov (*USSR*), Béla Csikós-Nagy (Hungary), Robert Gardiner (Ghana), Herbert Giersch (Federal Republic of Germany), Harry Johnson (United Kingdom), Ryutaro Komiya (Japan), Erik Lundberg (Sweden), Joszef Pajestka (Poland), and Raul Prebisch (Argentina). The program provided for papers and reports in plenary sessions and for papers and general discussion in ten separate working groups. Approximately 1,800 economists from 77 countries attended and over 500 participated in the discussions. The program contained the names of 82 economists (from 42 different countries), 53 as authors or coauthors of main papers, discussion papers, and opening statements, and 29 as chairmen or vice-chairmen of sessions and working groups. The largest delegation came from the *USSR* with 280 members. The United States was represented by 78 participants; of these the following six presented papers or discussion papers: Bela Balassa, Richard Cooper, Gottfried Haberler, Peter Kenen, Fritz Machlup, and Robert Mundell. This was the Fourth World Congress of the International Economic Association; the previous congresses had been held in Rome (1956), Vienna (1962), and Montreal (1968). Future congresses will be held every third year, the next one, 1977, in Tokyo.

The workshop at the Bosphorus University in Istanbul, Turkey, was held September 2 to 6 on "Population and Development." The Program Committee consisted of Paul Demeny as chairman and Emre Gönensay (Turkey) and Frederic C. Shorter as members. It was attended by twenty-seven persons, of whom fourteen came from Asia, five from Africa, four from Europe (three of them from socialist countries), and one from South America. From the United States, Paul Demeny, Frederic Shorter, and Jeffrey McNicoll were present.

The East-West Conference was held from August 29 to September 3 in Montreaux, Switzerland, on "Recent Economic Developments in Socialist and Non-Socialist Countries." It was arranged by John T. Dunlop. Of the nineteen participants, eight came from Eastern and eleven from Western countries. From the United States, Abram Bergson, James Duesenberry, John Dunlop, Walter Galenson, and Fritz Machlup attended.

The plans for 1975 include a conference

on "The Microeconomic Foundations of Macroeconomic Theories," to be held near Barcelona, Spain, in April, planned by a Program Committee chaired by Geoffrey Harcourt (Australia), assisted by Sir John Hicks and four others; a conference on "The Organization and Retrieval of Economic Knowledge" in Kiel, Germany, in July, arranged by a committee with Herbert Giersch (Federal Republic of Germany) and Mark Perlman as cochairmen; and a conference on "Inflation Theory and Anti-Inflation Policy" in Saltsjöbaden, Sweden, at the end of August, programmed by a committee chaired by Erik Lundberg (Sweden).

Five volumes of proceedings were published during 1974: *Agricultural Policy in Developing Countries*, edited by Nurul Islam; *The Economics of Health and Medical Care*, edited by Mark Perlman; *The Economic Development of Bangladesh*, edited by E. A. G. Robinson and Keith Griffin; *The Management of Water Quality and the Environment*, edited by Jerome Rothenberg and Ian G. Heggie; and *Industrial Management: East and West*, edited by Aubrey Silberston and Francis Seton. The first four volumes were published in London by Macmillan and in New York by the St. Martin's Press. The fifth volume was published in New York by Praeger Publishers. Several other volumes are at the printers or in preparation.

The officers of the Association for the next three years are Edmond Malinvaud (France), President; Shigeto Tsuru (Japan), Vice-President; and Herbert Giersch (Federal Republic of Germany), Treasurer.

FRITZ MACHLUP

REPORT OF THE REPRESENTATIVE TO THE NATIONAL BUREAU OF ECONOMIC RESEARCH

During 1974, research operations began at the new office of the National Bureau of Economic Research-West in Palo Alto, California, under the codirectorship of Victor Fuchs and Sherman Maisel. By the end of the year, some thirty staff members and associates were at the new facility, many having transferred from the New York office. Two special conferences were held on the West Coast, dealing with Regional Stock Exchanges in a Central Market System and International Trade, Finance, and Development of Pacific Basin Countries. In addition to branch offices already established in Cambridge, Mass., and New Haven, Conn., an office was opened in Washington, D.C. to accommodate ten staff members and associates conducting research and conference programs in that area.

The research program during the year included more than one hundred individual projects. Reports on their status appear in the National Bureau's 54th Annual Report, September 1974, which may be obtained from the Bureau on request (261 Madison Ave., New York, N.Y., 10016).

The National Bureau was involved in three major conferences in 1974, the proceedings of which will be published. Future conferences are to be held on the Economics of Urban Spatial Structure, Gregory K. Ingram, Chairman; Economic Analysis of Political Behavior, Melvin W. Reder, Chairman; Causes and Economic Effects of Population Change in Less-Developed Countries, Richard A. Easterlin, Chairman; and Low-Income Labor Markets, Sherwin Rosen, Chairman. In addition, there were eight workshops centered about the use of the computer, including three in Latin America, and eleven working groups operated through the Conference on Econometrics and Mathematical Economics.

At the request of the National Science Foundation, the National Bureau undertook a new activity to assist in the development of a United States-*USSR* Program on Scientific and Technical Cooperation. The Bureau is helping plan and coordinate the fields of econometric modeling, economic programming, and computer analysis applied to the economics and management of large systems. Joint meetings were held in each country in 1974 and further meetings and exchange visits by specialists are planned for 1975.

A new quarterly journal, ***Explorations in Economic Research***, was inaugurated with the first two numbers issued in September and December, 1974. This journal is designed to present staff research reports of the type that were formerly published as occasional or technical papers. In addition to major articles, the journal will regularly present a summary of the American Statistical Association-National Bureau of Economic Research Business Outlook Survey.

At the Annual Meeting on September 30, 1974, J. Wilson Newman was elected Chairman of the Board succeeding Walter W. Heller, Moses Abramovitz was elected

Vice-Chairman, and John R. Meyer was reelected President. Eli Shapiro had been elected a Director-at-Large, filling the vacancy created by the death of Eli Goldston. New Directors-at-Large elected at the Annual Meeting were Andrew F. Brimmer succeeding J. Irwin Miller, Frank L. Fernbach succeeding Joseph A. Beirne, and Rudolph A. Oswald, succeeding Boris Shiskin. Paul W. McCracken was elected Director Representative of the American Statistical Association. Among Directors by University appointment, J. C. La Force, University of California, Los Angeles, was elected to succeed Thomas A. Wilson, University of Toronto. At the end of 1974, Hal B. Lary retired from his position as Vice President-Research.

WILLARD L. THORP

REPORT OF THE CENSUS ADVISORY COMMITTEE

The Census Advisory Committee met twice during 1974 (April 11–12, and October 17–18). On each occasion, Vincent P. Barabba, Director, and other members of the Census Bureau staff presented a variety of reports concerning long- and short-range Census projects and problems. The Committee provided the Census Bureau with a number of specific recommendations with respect to individual projects, data collection techniques, and program development. Copies of specific recommendations can be obtained from the Director or the Committee Chairperson. In addition, at the October meeting two subcommittees were established as follows: Review of Overall Plans for Economic Censuses—Anne P. Carter, Chairperson; and Measurement of Inventories—Andrew F. Brimmer, Chairperson.

Additional committee members will be appointed to these subcommittees at a later date, and subcommittee chairpersons will be in contact with other members of the Association with respect to problems and suggestions. Voluntary responses for Association members are hereby solicited and may be sent to each subcommittee chairperson directly. Comments or suggestions of Association members with respect to the Census Bureau in general or with respect to other specific areas of study may be sent to the committee chairperson at any time.

The following Committee members complete their terms of service at this time: Guy E. Noyes, Jacob Mincer, Patricia Shontz, Phyllis A. Wallace, and the current chairperson. The Committee will be chaired for 1975 by Richard Ruggles.

LEE E. PRESTON, *Chairperson*

FOREIGN TRADE REGIMES AND ECONOMIC DEVELOPMENT

JAGDISH N. BHAGWATI and ANNE O. KRUEGER, Editors

This ambitious research project sponsored by NBER analyzes the phenomena of exchange control, liberalization, and economic development in less developed countries. There will be ten volumes published on individual countries plus a synthesis volume prepared by the co-directors, Jagdish N. Bhagwati and Anne O. Krueger.

The three major topics covered in each country studied are: the Anatomy of Control, the Liberalization Episode, and Growth Relationships.

The first two volumes in the series are:

Volume 1: Turkey, by Anne O. Krueger
cloth, $17.50; paper, $5.00
Volume 2: Ghana, by J. Clark Leith $15.00

A Special Conference of the National Bureau of Economic Research

ESSAYS IN THE ECONOMICS OF CRIME AND PUNISHMENT

GARY BECKER and WILLIAM LANDES

The distinguishing and unifying feature of the essays in this volume is the systematic study of enforcement as an economic problem. Subjects covered include optimal enforcement, optimal bail system, and the development of a positive theory of legal decision making as applied to enforcement decisions.

Human Behavior and Social Institutions, 3
cloth, $12.50; paper, $3.50

INCOME INEQUALITY

Regional Analyses Within a Human Capital Framework

BARRY R. CHISWICK

This human capital analysis focuses on differences in the amount of investment in schooling and in the rate of return from this investment to explain variations in inequality of labor income in the United States and other countries.

Human Behavior and Social Institutions, 4 $15.00

COLUMBIA UNIVERSITY PRESS

Address for orders: 136 South Broadway, Irvington, New York 10533

PEOPLE OR PENGUINS

The Case for Optimal Pollution

WILLIAM F. BAXTER

Transcending the fuzzy thinking and emotional rhetoric associated with environmental discussion, Professor Baxter has provided an engagingly written assessment of the legal and economic questions which lie at the heart of all pollution problems. cloth, $6.00; paper, $1.95

THE FAILURE OF U.S. ENERGY POLICY

RICHARD B. MANCKE

Present energy policy was designed by officials who have misperceived our world, Dr. Mancke maintains in this scathing indictment. His analysis is bolstered by historical case studies and supplemented by reform programs for the future. cloth, $10.00; paper, $2.95

INTRODUCTION TO MANAGERIAL ECONOMICS

WILLIAM F. SHARPE

How much economic theory should the modern business manager know? Developed from ideas first presented in Sharpe's highly-praised *The Economics of Computers,* this book provides in concise form all the basics the student or working manager will require, and supplies the necessary background for more complex analyses.
cloth, $10.00; paper, $3.50

SEX, DISCRIMINATION, AND THE DIVISION OF LABOR

CYNTHIA B. LLOYD, Editor

This collection of sixteen essays looks at the role of women in the labor market, touching on the areas of productivity, participation, and compensation, among others. These essays will be valuable to the student or individual with only a basic knowledge of economics as well as to students of economic research and teachers of courses on women.

Studies in Economics, 8 cloth, $15.00; paper, $6.00

Ready in May for your fall courses.

Write today for examination copies for fall course adoption.

IASP TITLES IN ECONOMICS

John Kenneth Galbraith and the Lower Economics

Second, Expanded Edition

Myron E. Sharpe, Editor of CHALLENGE: The Magazine of Economic Affairs

"The best review I have yet seen of Galbraith's works . . . Sharpe (in the first edition) has succeeded in highlighting Galbraith's contribution to economic thought, while exposing to critical scrutiny the weakest parts of his analysis. I'm happy to recommend this book." **—Robert L. Heilbroner**

This edition contains a new section evaluating Galbraith's *Economics and the Public Purpose*, and includes a lengthy interview with Galbraith. $7.95

The Socialist Economies of the Soviet Union and Europe

Marie Lavigne, University of Paris

"Marie Lavigne's book is both thoroughly competent and of a sufficiently high standard to raise French Sovietology to the level of English or American works on the same subject." **—Revue Economique** **(Reprinted in Economic Journal)**

This encyclopedic study devotes major attention to the Soviet economic system, and is unusually detailed in describing the other socialist economies and in drawing upon them for important cross-national comparisons.

Dr. Lavigne's publications include *Capital in the Soviet Economy, The Problem of Prices in the Soviet Union* (with Prof. H. Denis), and *COMECON: From Cooperation to Integration of the Socialist Economies.* $20.00

Land Reform and Economic Development in China

A Study of Institutional Change and Development Finance

Victor D. Lippit, University of California at Riverside

A new analysis that makes a significant contribution to the economics of the Chinese Revolution and to development theory generally.

Professor Lippit shows how a poor country managed simultaneously to raise the share of national income devoted to investment and increase living standards. He focuses on the use of the "surplus" — the capital or property share of national income — to redirect income flows, thereby to shift consumption from luxuries to necessities and increase public investment. $15.00

Essays in Honor of Jan Tinbergen

Edited by Willy Sellekaerts, The Wharton School, University of Pennsylvania

Three volumes of original articles by some of the world's leading economists. Each volume includes a selected bibliography of Tinbergen's work, as well as an introduction which appraises Tinbergen's major contributions to economics. The three volumes are: *International Trade and Finance; Economic Development and Planning; Econometrics and Economic Theory.* $20.00 per volume

The Strategy of International Development

Essays in the Economics of Backwardness

H. W. Singer

Edited by Sir Alec Cairncross and Mohinder Puri

This volume contains H. W. Singer's most important papers of the past five years on the central problems of economic development. The collection presents the author's current views after more than twenty-five years of study and direct involvement with many of the developing countries.

Sir Alec Cairncross has written a substantive introduction that reviews Dr. Singer's distinguished career and examines in some detail the role of technological development in economic growth. $20.00

Self-Governing Socialism: A Reader

Edited by Branko Horvat, Mihailo Marković and Rudi Supek

Three distinguished Yugoslav scholars have selected seminal articles, book extracts, and documents from 20 countries in order to trace the theory and practice of self-governing socialism from the early nineteenth century to the present. Much of the material is being made available in English for the first time. Volumne I: *Historical Development; Social and Political Theory.* Volume II: *Sociology and Politics; Economics.*

Vol. I (cloth)	$21.50	Vol. II (cloth)	$18.50
(paper)	$9.50	(paper)	$7.95

Monetary Cooperation Between East and West

Adam Zwass, Vienna Institute for Comparative Economic Studies

Foreword by George Garvy

A systematic study of the instruments and processes of East-West financial relations based on a critical analysis of the money, credit and foreign trade systems of the East European countries and of their Council for Mutual Economic Assistance.

Dr. Zwass occupied managerial positions in the central banking systems of Poland and the USSR. From 1963 to 1968 he was a Counsellor in the COMECON Secretariat in Moscow, where he was responsible for the work of the International Bank for Economic Cooperation. $15.00

Psychological Economics

By GEORGE KATONA.

Consumer behavior is shown to be of crucial importance in today's economy. During the last few decades in all highly developed economies, consumers have acquired great discretion in spending and saving. Changes in their attitudes and expectations, determined through sample interview surveys, help us to understand and predict upswing or downswing in the economy as well as the extent of inflation. The book's timeliness is exemplified in the coverage of such problems as the psychology of inflation and the possible limits to growth. **1975. 352 pages. $13.00**

Games for Society, Business and War

TOWARDS A THEORY OF GAMING

By MARTIN SHUBIK.

Designed primarily for those interested in gaming, this original and timely book is an overall survey in which the difference between gaming and the theory of games is clearly distinguished. It provides a unified view of both the theory and usage of gaming for teaching, research, business, military science, social psychology and other purposes. Chapters discuss and illustrate such topics and areas as: the revelance of simulation, behavioral models of systems, mathematical and game theory models of conflict and cooperation. **1975. 380 pages. $16.50**

The Uses and Methods of Gaming

By MARTIN SHUBIK.

A companion volume to *Games for Society, Business and War*, this guide presents information on the many types and purposes of gaming. Designed for those who wish to construct games, it stresses how to set up, to cost, and to run games. In addition, it tells where to find the basic literature and information on gaming and related topics. **1975. 208 pages. $12.00**

Human Behavior in Economic Affairs

ESSAYS IN HONOR OF GEORGE KATONA

Editors: BURKHARD STRUMPEL, JAMES N. MORGAN, and ERNEST ZAHN.

George Katona is renowned as the pioneer in the development of psychological economics and the 25 essays assembled here are written by prominent people in related fields. The essays evaluate and review the progress and success of the behavioral economic science, stressing the power of an interdisciplinary approach to the understanding of the behavior of the householder as consumer. **1972. 590 pages. $18.75**

Efficiency in Universities

THE LA PAZ PAPERS

By KEITH LUMSDEN.

The crucial question of how university efficiency can be improved is dealt with in this volume. In practice, the management of universities is carried out by administrators who depend largely on government funding and/or private donations, and each tries to use the university as a means of furthering its own objective. Various other facets are treated in this volume, including defining different functions of the university, improving efficiency through reorganization and the introduction of new techniques. **1974. 278 pages. $15.95**

Advertising Planning

MATHEMATICAL MODELS IN ADVERTISING MEDIA PLANNING

By DENNIS H. GENSCH. **1973. 176 pages. $12.50**

Environmental Quality: The First Five Years

By EDWIN S. MILLS AND FREDERICK M. PETERSON*

On January 1, 1970, President Nixon signed the National Environmental Policy Act (*NEPA*). Explicitly modeled on the Employment Act of 1946, *NEPA* established the Council on Environmental Quality (*CEQ*) in the president's executive offices to advise the president on environmental issues as the Council of Economic Advisers (*CEA*) advises him on economic issues. Just as *CEA* is required to submit to the president, *The Annual Report of the Council of Economic Advisers* (*ER*), so *CEQ* must submit an annual report, *Environmental Quality* (*EQ*).

Each year since 1971, this *Review* has devoted part of an issue to comments on *ER*. But despite the substantial and growing interest of economists in environmental problems, the profession has taken little notice of successive volumes of *EQ*. The purpose of this paper is to use the occasion of the publication of the fifth volume of *EQ* to bring this important publication to the attention of the economics profession. We start with a brief comparison between *CEQ* and *CEA*, then present an overview of *EQ*, and finally a review of its economic analysis.

I. Organizational Background

CEQ and *CEA* are in many ways similar organizations. Each consists of three members appointed by the president, with one member designated chairman. Each is served by a staff that includes about twenty-five professionals. Each not only advises the president, but also advises, cajoles, and intermediates among operating agencies of the federal government. There are two important differences between *CEQ* and *CEA*.

First, whereas *CEA* and its professional staff are, quite properly, almost all economists, *CEQ* and its staff are, also properly, drawn from a variety of professional backgrounds. Nevertheless, an economist is struck by the paucity of economic input at *CEQ*. No economist was among those appointed by President Nixon to *CEQ* and they have always been a tiny minority on its staff. Although both *CEA* and *CEQ* have had rapid and probably desirable turnover of their members and staffs, many *CEQ* personnel have pursued large parts of their careers in government whereas many *CEA* personnel are on leave from universities and research institutions.

Second, whereas *CEA* is entirely a staff organization, *CEQ* has an important operational responsibility. The act (*NEPA*) instructed all federal agencies to " . . . include in every recommendation or report on proposals for legislation and other major Federal actions significantly affecting the quality of the human environment, a detailed statement by the responsible official on—(i) the environmental impact of the proposed action. . . . " Congress must have written this directive while distracted by other matters. It has led to endless litigation—so much so that it is referred to as the lawyers' relief bill—stemming from the failure of Congress to specify how the impact statements should relate to other laws that incorporate environmental considerations into decisions;

---

* Princeton University and the University of Maryland, respectively.

who if anybody should receive and read the statements; and what, if any, effect the statements should have on decisions taken. In any case, it has fallen to *CEQ* to evaluate impact statements. This task now occupies the time of a substantial minority of *CEQ* staff. Indeed, tracing and disentangling *NEPA* and its impact statements have occupied a substantial part of the five volumes of *EQ*.

II. An Overview of *Environmental Quality*

EQ and *ER* are intended to serve three purposes. First, they provide a systematic survey of trends and conditions regarding the environment and the economy. The first chapter of *ER* always surveys trends in the economy's output, employment, prices, etc. Likewise, each issue of *EQ* contains a chapter that discusses recent trends in air and water pollution, solid waste disposal, etc.

Second, they serve the educational purpose of providing the informed public with a systematic and coherent analysis of problems of urgent social concern. *ER* frequently presents analyses of causes and consequences of economic problems and of the pros and cons of alternative government policies to deal with the problems. Aside from the perennial problem of economic stabilization, frequent candidates for analysis are balance of payments, agriculture, poverty, and industrial organization and regulation. In the same vein, *EQ* provides frequent analyses of environmental and related problems. There are annual discussions of government policy developments toward air and water pollution and solid waste disposal. There are frequent sections on pesticides, radiation, and noise, and occasional sections on energy and natural resource adequacy. In addition, *EQ* sometimes presents a case study of a particularly instructive attempt to clean up a river or estuary.

Third, *EQ* and *ER* are intended to present and defend the president's program in their areas of concern. In *ER*, this purpose is served by methods varying from hints and suggestions on future directions for fiscal and monetary policy to full chapters laying out strategy for the war on poverty. In *EQ*, the third purpose has been of decreasing importance. The first volume (1970) had a concluding chapter that laid out boldly a list of environmental policy "needs." The second volume (1971) had a competent and favorable discussion of the advantages of effluent fees as a tool of environmental policy. But the last three volumes have had almost no discussion of alternative policies, except occasional favorable comments on specific bills previously proposed by the president. One gets the strong impression that *EQ* has become very much the status report of *CEQ* and very little the policy statement of the administration.

The first purpose is carried out in an almost entirely nonpolitical way in both *ER* and *EQ*. Despite occasional slips, *ER* and *EQ* have reported past trends with remarkable objectivity and with remarkably little attempt to put one administration or another in a particularly good or bad light.

The second purpose tends to be executed with considerable delicacy, but also with considerable objectivity. Usually, the issue seems to be how specific the professionals who write the reports are permitted to be by the administration regarding conclusions for government policies to solve problems. This sometimes causes analyses and conclusions to be vague or evasive and studded with circumlocution, but examples of blatantly partisan analysis of policy problems are remarkably rare in both *ER* and *EQ*. Partisan-minded readers can, however, see considerable political influence in choice of topic. The best example of this is the treatment of poverty in *ER*. A long section or chapter on poverty had become *de rigueur* in the Democratic administrations' *ER*'s starting in 1964. But the first discussion of poverty in the five *ER*'s submitted to President Nixon appeared in his last *ER* (1974). Partisan influences on choice of topic are harder to identify in *EQ* since we have not yet had a Democratic report. But the five Republican *EQ*'s have devoted considerable attention to initiatives of state and local governments to clean up the environment. It seems certain that this attention has been inspired more by the administration's desire to deemphasize the federal role than by the meagre initiatives reported, and that state and local initiatives would have received less attention in *EQ*'s produced by Democratic administrations.

The third purpose is of course explicitly political, and partisanship is to be expected. In fact, *EQ* has been remarkably objective in discussing the president's environmental programs and his frequent battles with Congress on the subject. The best example of this contention is the controversy surrounding the 1972 amendments to the Water Pollution Control Act. This was certainly the most important environmental legislation of the Nixon presidency and was passed over his veto. Although he agreed with many of its complex substantive provisions, he felt the large sums it provided for municipal waste treatment plant construction were inflationary. After it was passed over his veto, he proceeded to impound large parts of its appropriations and there followed an intense political and legal battle. The 1973 *EQ* has an extended factual discussion of these matters and contains no hint of recrimination or partisanship.

Economists accustomed to *ER* inevitably feel that *EQ* is long and diffuse. In fact, *EQ* is a long report. Its 1974 issue was 597 pages, two-thirds longer than the 1974 *ER*. Both *EQ* and *ER* grew during the Nixon years, but *EQ* grew more rapidly. The fifth issue of *EQ* was 82 percent longer than the first. In part, *EQ* is long because of the broad definition *CEQ* has given to the term environment. When economists discuss environmental problems they invariably refer to the effects of materials discharges in the course of extraction, fabrication, and consumption, on the quality of the ambient air and water environments. Laymen and other professionals sometimes use the term more broadly, and *CEQ* appears to have adopted the broadest possible definition. They have discussed the adequacy of fuel and other natural resource reserves as well as effects of their extraction and combustion on air and water environments; the urban environment, including aesthetic effects of building size, design and location, the functions of downtowns, and urban renewal; urban land use, including effects of urban decentralization or sprawl; national parks; population problems; and details regarding the organization and administration of the federal government's environmental program. The effect on *EQ* is to make the report long and confusing.

The effect of the broad definition of the subject would not be so serious if *EQ* were better organized. The minimum that the reader ought to be able to expect from *EQ* is a clear and concise presentation of environmental trends and status. There should be one chapter or section each for air, water, and solid wastes, and they should appear consistently near the front of the report. Each should discuss the status and trends of discharges, ambient environmental quality, and effects of pollution on people and property. Great pains should be taken each year to update and improve an intelligible and meaningful set of quantitative measures of discharges and of ambient quality.

In fact, the first (1970) *EQ* started off to do just that. But in the second (1971) volume, one had to go to chapter 7 for such data. In the third (1972) volume, the presentation of comprehensive data was abandoned altogether, and a discussion of uninformative environmental indices was substituted. The fourth (1973) volume reverted, in chapter 6, to a report on trends. The indices discussed the previous year were blessedly abandoned, but much of the ambient data were presented as ratios to federal standards. The fifth (1974) volume presented, in chapter 3 this time, a good discussion of airborne discharges and ambient air quality, but almost entirely in graphs rather than tables, making it difficult to read precise values. The water data are much poorer despite the fact more water than air data are available.

The presentation and discussion of data should be followed by a discussion of policy changes and developments with regard to air, water, and solid waste. If this format were followed, each report could then also include one or more chapters on some of the special topics mentioned above, especially if *CEQ* had something to say about their relationship to air and water quality. Instead, the central chapters on environmental trends have been located in every part of *EQ* and, in some reports, the special topics have been made the focus of the report.

Closely related to the above discussion is the issue of data. One of the charges to *CEQ* in *NEPA* is to improve the collection and publication of data on environmental quality. Everybody knows that data on environmental quality are inadequate, and we do not want to add to the chorus of complaints on the subject. But the fact is that data on environmental quality have improved greatly during the last five or so years, and *U.S.* data are as good and plentiful as those in almost any country. Rather, our complaint is that *EQ* should have started at the beginning to present, preferably in a statistical appendix, summaries of available data, updating the series as new data became available. They should have devoted considerable effort to presenting data in consistent and informative ways. They should explain what the data mean, how they are compiled, where additional detail can be found, and how the data can be compared when series are changed or expanded. Finally, *EQ* should indicate gaps and inadequacies in the data.

ER has of course contained a statistical appendix for years. Although the original sources of the data are not dispersed or obscure, the *ER* appendix is invaluable as a ready reference for overall economic trends. Environmental data, in contrast, are dispersed and inaccessible. A good statistical appendix to *EQ* would be even more valuable than that in *ER*. The most important data to present are averages of discharges and ambient air and water quality. Data should be neither excessively detailed nor excessively aggregated. The most detailed data can be obtained from the original sources and do not need to be published in *EQ*. If *CEQ* undertakes or supports studies of environmental indices, they can be presented, but they should be in addition to the more basic data rather than instead of them.

The 1974 *EQ* makes a belated and inadequate attempt at an environmental statistical abstract. Of the thirty tables presented, only the last five pertain to discharge quantities or to ambient air and water quality. The others, like the texts of *EQ*, are a miscellany of data on agriculture, minerals, energy, population, wholesale prices, etc. There is little harm in including some of this information, but it is presented without organization and with no apparent thought as to what to include. Much more important, of the five tables relating to pollution, not one provides direct measures of ambient air or water quality. We are given only numbers of stations at which ambient air and water quality did or did not meet standards set by the government. It is shocking that the ambient air and water quality data presented in *EQ*'s statistical appendix are even worse than those presented in the *Statistical Abstract*.

Lest it be thought that we are setting a standard for *EQ* that is theoretically desirable but practically unattainable, we refer briefly to the analogous Japanese publication, *Quality of the Environment in Japan*. Japan's basic environmental data are certainly no better than those available in the *U.S.* The Japanese passed their first comprehensive antipollution laws long after we passed ours and they have had less experience in writing their annual environmental report than we have. Yet their report is only half as long as ours (at least in its English language version), less cluttered with peripheral issues, less redundant, better organized and better documented with intelligible and meaningful data. We do not set the Japanese report as an ideal. There are many things wrong with it, but we do not think it unreasonable to expect the *U.S.* report to be as good as the Japanese. Yet it is not.

III. Economic Analysis in *Environmental Quality*

We come now to the central issue, the kinds of economic analysis in *EQ*. Economics is of course only one part of the process of government policy making toward the environment. The metering of discharges and of ambient environmental quality, the measurement of damages done by pollutants, the analysis of physical measures to abate discharges and to reduce their polluting effect on the environment, and the analysis of the environmental effects of a wide range of government activities all require the work of physical and biological scientists and of engineers.

Yet environmental problems and remedial government policies cannot be analyzed satisfactorily without a substantial input of economic analysis. We find it useful to classify economic analyses of environmental problems into three categories. First is the study of market failure, why and in what circumstances private production and consumption of goods and services result in excessive or excessively harmful discharges of materials to the environment. Second is benefit-cost studies of varying amounts of pollution abatement. Third is government program evaluation. All government programs to improve environmental quality entail complex interactions between government and private sectors. Each possible program has peculiar effects on the ways private markets allocate resources, and such effects are difficult to foresee without careful analysis. In addition, some government programs are much easier or cheaper to administer than others, and provide varying incentive structures for the agencies that administer them. Analysis of these issues is somewhere around the fuzzy borderline between economics and public administration.

The tools in the economist's box are of course by no means perfect for these purposes and it is now fashionable for economists to beat their breasts about their inadequacy. Much of this is overdone. The basic reasons for market failure regarding polluting discharges were well known to Pigou and have become even better understood as a result of sharper analysis in the last decade or two. Benefit-cost analysis, although currently out of favor in the national government, has been developed into a sophisticated tool of evaluation. Program evaluation remains more an art than a science, but a great deal of research has been undertaken about the efficacy and implications of alternative government programs to induce private decision makers to abate polluting discharges. Our overall evaluation is that environmental problems have been better studied and are better understood than most micro-economic public policy issues. We first evaluate the use made of economic analysis in *EQ* to shed light on government antipollution policy. We then conclude the section with brief comments on the use of economic analysis to understand other problems discussed in *EQ*.

The space devoted to economic analysis in the first five volumes of *EQ* is extremely small. For a publication that has printed the text of *NEPA* five times, printed and reprinted executive orders and administrative guidelines, traced the development of relatively minor changes in government programs in endless detail, and sometimes discussed the same topics and data in two or three places in one volume, the economic analysis is remarkably brief and isolated. (The only exception to this is the repeated discussion of pollution control costs, which we refer to below.) It is almost as though economists had been given a quota of a few pages in each volume, and that other parts of the volume, especially those surveying the development of government policies, had been written by others without reference to what the economists wrote. Despite this, *EQ* contains some good micro-economic analysis, certainly on a par with most of that contained in *ER*. In fact, there is a distinct and rather logical development of the economic analysis in successive volumes of *EQ*.

The first chapter of the 1970 volume of *EQ* contains the best overall picture of environmental problems we have seen in a government report published up to that time. This chapter contains a competent discussion of the basic economic cause of pollution, market failure because polluting discharges are an external diseconomy. But the discussion is less than one page! By contrast, the chapter is followed by a 10-page description of the organization of the federal government for pollution control, and then by more than 100 pages on the physical and biological aspects of pollution. No indication is given in these pages how economics might be used to shed light on the pollution problems discussed, on the costs and benefits of solving them, or on the efficacy of possible government programs to do so.

The 1971 volume of *EQ* contains a much more elaborate discussion of basic environmental economics, this time in chapter 4. It starts with a careful discussion of market failure regarding the environment, emphasizing the failure of usual market incentives properly to value common property resources—the ambient air and water environments. It then presents a frank and thorough survey of what little is known about the benefits of pollution abatement. This is followed by a much longer survey of the richer body of evidence about the costs of pollution control. Both the benefit and cost surveys cover government and private estimates objectively, carefully distinguishing among average and marginal costs and benefits. They conclude with a comparison between costs and benefits, suggesting where they think the balance lies, but frankly admitting the inability of existing studies to sustain a conclusion about the optimum amount of abatement. Finally, they present a remarkably good evaluation of alternative pollution abatement strategies. They rightly concentrate on discharge standards and effluent fees as the two most important candidates for pollution control strategies. They do not come down nearly as hard on the side of effluent fees as most academic economists do, but their conclusions are as firm as can be expected given that national policy depends entirely on discharge standards. They advocate a balanced use of standards and fees. This is to be applauded as a piece of bravery within the national administration, but as a policy, it would probably achieve the worst of both worlds.

The 1972 volume of *EQ* contains a chapter (8), devoted entirely to the costs of pollution control. It expands and updates the cost data in the 1971 volume. *CEQ*'s survey takes only about twelve pages. At that point the chapter is broken and the remainder of the chapter is a reprint of the overview of a large interagency study of the economic impact of pollution control. This produces an unsatisfactory discontinuity in the text. The studies summarized consist of micro studies of eleven important industries and a macro study. The micro studies analyze the effects of pollution control requirements on prices, investment, output, employment, and international competitiveness during the period 1972–76 in the eleven industries. It is hard to believe the results are very accurate in detail, but the overview is probably correct in concluding that the pollution control requirements then in effect would not cause very serious dislocations in most industries. The macro study includes public and private pollution control expenditures in a macro-econometric model and concludes, predictably, that their effects can be offset by changes in fiscal and monetary policy. Practically all the cost analyses in the 1972 volume of *EQ* were rendered obsolete by the passage of the 1972 amendments to the Water Pollution Control Act a few weeks after the report appeared.

The 1973 volume again includes a full chapter (3) of economic analysis. This time, as in 1971, both benefits and costs of pollution control are included. The conceptualization of the benefit-cost analysis is remarkably sophisticated. On the benefit side, the distinction is made between reductions in damages from pollution and reductions in costs of avoiding pollution damages. The data are still poor in comparison with available cost data, but the survey is competent. On the cost side, the distinction is made between abatement costs and transaction costs (the costs of administering pollution control programs), and the cost estimates are updated to take account of the more stringent requirements of the 1972 water quality amendments. In this volume, in contrast with the 1971 volume, no attempt is made to put the cost and benefit estimates together to estimate the abatement level at which they might be equated at the margin. It seems clear that the elaborate 1973 cost estimates were undertaken defensively, in response to growing industry complaints that the 1970 air and 1972 water amendments would impose large dislocations on the economy. Hence, *CEQ*'s interest was not so much in comparing benefits and costs as in showing that the economy could afford the costs. Unfortunately, the 1973 volume contains no program evaluation. A short section on economic incentives merely points out a few of many undesirable incentive effects of our regulatory program. But there is no discussion of effluent fees or of other alternatives to the regulatory program.

Unfortunately, economic analysis of pollution problems is nearly absent from the 1974 *EQ*. We are given only a five-page update in chapter 2 of estimated abatement costs during the 1973–82 period. These most recent estimates are that federal antipollution programs cost the *U.S.* economy $6.3 billion in 1973 and that existing legislation will impose an average cost of about $20 billion per year on the economy during the 1973–82 period. *EQ* is content merely to point out that the former figure is about .75 percent of the 1973 *GNP* and the latter about 1 percent of the average projected *GNP* during the decade. But $20 billion per year is a lot of money, and it now becomes extremely important to ask whether these expenditures are justified by comparable benefits and whether the benefits could be obtained more cheaply by alternatives to existing programs. Thus it is extremely unfortunate that *CEQ* has backed off from benefit estimation and program evaluation when we are clearly moving onto the rapidly rising part of the marginal abatement cost curve.

We evaluate *EQ*'s environmental economic analysis under the following four headings.

1. In one volume or another, *EQ* has presented as good a menu of economic analyses of environmental problems as can be expected in the short space devoted to it. But the space allocated to economic analysis is too small to do justice to the complex issues involved. The severe space constraints can hardly be explained by overall space constraints since space is treated like a nearly free good in most of the report.

2. The most serious criticism of the economic analysis in *EQ* is that it is isolated from the rest of the report. For example, the 1971 volume presents a good section on program evaluation, but there is no evidence the analysis there presented has had any effect on the interminable histories of government policy changes that have been presented. Clearly, the section on program evaluation should establish the framework within which program development will be discussed. Instead, *EQ* treats economists as an interest group which must be mollified, as many interest groups are mollified in government reports, by including a section on a subject dear to their hearts.

3. We are disturbed at the trend in recent volumes to restrict economic analysis to whether the economy can "afford" the government's program of pollution abatement. This is not a very challenging economic issue. There can be no doubt that the *U.S.* economy can afford $20 billion, or $50 billion, per year on pollution abatement, provided urgent benefits to health and welfare are contingent on the expenditures. The important issues, for the public and for economists, are whether the costs are justified by comparable benefits and whether existing programs are the most efficacious ways to obtain the benefits.

4. Closely related to the previous point is the tendency to slight benefit estimation. *CEQ* and other federal agencies concerned with the environment have lavished large sums of money on pollution abatement cost studies. But the benefit side has been sadly neglected. Benefit studies are of course more difficult than cost studies, but that is justification for more rather than fewer resources devoted to them since public policy cannot possibly be set without explicit or implicit benefit estimates. Some careful benefit studies have been undertaken, especially regarding auto pollution control, in recent years, but they have come from universities, private research institutions, and the National Academy of Sciences. The tendency in government and, sad to say, sometimes among economists is to claim that economics can be applied to the cost side of pollution control but that the benefit side is necessarily a "political issue." In a democracy, both benefit and cost estimates are quite properly cast into law and administrative procedures by the political process. The purpose of expert advice is to edify the process. There is no reason to believe that economists can be of less help on the benefit than on the cost side.

It was mentioned in Section II that many subjects in addition to pollution are addressed in *EQ*. We conclude this section with brief comments on the use of economics in analyzing these issues. For some of these issues, it is quite justified that the analysis contains no economics. For example, each volume of *EQ* contains some discussion of international aspects of pollution. Subjects discussed include polluting discharges that move across national boundaries, pollution of the oceans, inadvertent modification of climate by man's activities, and cooperation among governments on environmental problems. Despite some recent work, there is at present relatively little that economists have to say on most of these subjects.

Land use, however, is a different matter. Each of the five volumes of *EQ* has a chapter or major section on some aspect of land use. Sometimes the subject is broadly construed, sometimes more narrowly in terms of urban or inner city land use. Sometimes the discussion is in terms of the intriguing relationships between pollution and land use, but more often it is in terms of land use and the spatial organization of economic activity. The level of economic sophistication in the discussion of land use is below that in the discussion of pollution problems.

The basic defect in the land use discussions is the absence of any analysis of market failure. Unlike its discussion of pollution, *CEQ*'s discussion of land use does not include an analysis of external diseconomies or other market failures that it believes create a problem for government policy. *EQ*'s discussion is clearly sympathetic to the notion of government controls on urban decentralization and urban growth. But it has no analysis that would inform readers why it thinks these historical trends are inefficient or inequitable. Instead, the discussion is pejorative and emotional. Suburbanization is explained in terms of the attitudes of the frontier society and of rural values. In fact, the process of urban decentralization has been studied at length by economists and geographers. It pervades the industrialized world and its main causes are widely believed to be rising real incomes and improved transportation. The process is not very different in the United States from other industrialized countries except that incomes are higher and relative prices of land are lower here than elsewhere. There is nothing in the process that suggests market failure. Most of the factors *EQ* points to as causes of urban sprawl are merely market responses to satisfy consumer demands. In the United States, the main reason to believe that urban decentralization has been excessive is that local governments have required excessively low suburban densities by large lot zoning and other land use controls.

Plenty of people can be found to disagree with the above analysis and *CEQ* is no more obligated to accept it than anyone else. But *EQ* merely ignores it and presents no coherent alternative analysis. This is far from an entirely academic issue since federal, state, and local government controls on urban growth and decentralization are now heated public issues. Pollution is only a relatively small part of this matter and there is grave doubt whether *EQ* is the appropriate place for a full discussion of the issues. At least, the analysis they have given does not persuade us.

IV. Conclusions

Our overall evaluation of *EQ* is that it has made a beginning at filling an important public need for a systematic discussion of environmental trends, status, and problems. We believe that the need can be filled much better if future volumes are shorter, better organized, and better focused on pollution problems, with somewhat less attention devoted to peripheral issues. *CEQ* should accord high priority to development of an adequate statistical appendix.

We believe that the economic analysis presented in *EQ* has been of good quality. It has been excessively abbreviated and appears to have had no effect on the discussion of policy developments in other parts of *EQ*. We are concerned at the recent tendency to adopt a defensive stance of restricting economic analysis mainly to demonstrations that the economy can afford existing government programs to abate pollution. Future *EQ*'s should revert to the earlier policy of evaluating benefits as well as costs of environmental programs, and more resources should be devoted to benefit estimation. Our first comprehensive water pollution control legislation was passed almost two decades ago and the analogous air legislation more than one decade ago. We should have a frank evaluation of what has and what has not been accomplished, and which programs have worked better than others. Finally, future volumes of *EQ* should continue the earlier environmental program evaluation that has been absent from recent volumes.

Short-Term Interest Rates as Predictors of Inflation

By Eugene F. Fama*

Irving Fisher pointed out that with perfect foresight and a well-functioning capital market, the one-period nominal rate of interest is the equilibrium real return plus the fully anticipated rate of inflation. In a world of uncertainty where foresight is imperfect, the nominal rate of interest can be thought of as the equilibrium expected real return plus the market's assessment of the expected rate of inflation.

The relationships between interest rates and inflation have been tested extensively.[1] In line with Fisher's initial work, the almost universal finding is that there are no relationships between interest rates observed at a point in time and rates of inflation subsequently observed. Although the market does not do well in predicting inflation, the general finding is that there are relationships between current interest rates and past rates of inflation. This is interpreted as evidence in favor of the Fisherian view. Thus Fisher concludes:

> We have found evidence, general and specific, . . . that price changes do, generally and perceptibly, affect the interest rate in the direction indicated by *a priori* theory. But since forethought is imperfect, the effects are smaller than the theory requires and lag behind price movements, in some periods, very greatly. [p. 451]

Fisher's empirical evidence, and that of most other researchers, is in fact inconsistent with a well-functioning or "efficient" market.[2] An efficient market correctly uses all relevant information in setting prices. If the inflation rate is to some extent predictable, and if the one-period equilibrium expected real return does not change in such a way as to exactly offset changes in the expected rate of inflation, then in an efficient market there will be a relationship between the one-period nominal interest rate observed at a point in time and the one-period rate of inflation subsequently observed. If the inflation rate is to some extent predictable and no such relationship exists, the market is inefficient: in setting the nominal interest rate, it overlooks relevant information about future inflation.

This paper is concerned with efficiency in the market for one- to six-month U.S. Treasury Bills. Unlike Fisher and most of the rest of the literature, the results presented here indicate that, at least during the 1953–71 period, there are definite relationships between nominal interest rates and rates of inflation subsequently observed. Moreover, during this period the bill market seems to be efficient in the sense that nominal interest rates summarize all the information about future inflation rates that is in time-series of past inflation rates. Finally, another interesting result is that the substantial variation in nominal bill rates during the 1953–71 period seems to be due entirely to variation in expected inflation rates; in other words, expected real returns on bills seem to be constant during the period.

[2] For a discussion of the theory of efficient capital markets and related empirical work, see the author.

The theory and tests of bill market efficiency are first presented for one-month bills. The results are then extended to bills with longer maturities.

I. Inflation and Efficiency in the Bill Market: Theory

A. *Returns and the Inflation Rate*

The nominal return from the end of month t−1 to the end of month t on a Treasury Bill with one month to maturity at t−1 is

$$(1)\qquad R_t = \frac{v_t - v_{t-1}}{v_{t-1}} = \frac{\$1{,}000 - v_{t-1}}{v_{t-1}}$$

where $v_t = \$1{,}000$ is the price of the bill at t, and v_{t-1} is its price at t−1. Since the bill has one month to maturity at t−1, once v_{t-1} is set, R_t is known and can be interpreted as the one-month nominal rate of interest set in the market at t−1 and realized at t.

Let p_t be the price level at t, that is, p_t is the price of consumption goods in terms of money, so that the purchasing power of a unit of money, the price of money in terms of goods, is $\pi_t = 1/p_t$. The real return from t−1 to t on a one-month bill is then

$$(2)\qquad \tilde{r}_t = (v_t\tilde{\pi}_t - v_{t-1}\pi_{t-1})/v_{t-1}\pi_{t-1}$$

$$(3)\qquad = R_t + \tilde{\Delta}_t + R_t\tilde{\Delta}_t$$

where tildes (˜) are used to denote random variables, and

$$(4)\qquad \tilde{\Delta}_t = (\tilde{\pi}_t - \pi_{t-1})/\pi_{t-1}$$

is the rate of change in purchasing power from t−1 to t. In monthly data, R_t and $\tilde{\Delta}_t$ are close to zero, so that although the equality only holds as an approximation, no harm is done if (3) is reduced to

$$(5)\qquad \tilde{r}_t = R_t + \tilde{\Delta}_t$$

Thus the real return from the end of month t−1 to the end of month t on a Treasury Bill with one month to maturity at t−1 is the nominal return plus the rate of change in purchasing power from t−1 to t.

The fact that $\tilde{r}_t$ is a random variable at t−1 only because $\tilde{\Delta}_t$ is a random variable explains why bills are attractive for studying how well the market uses information about future inflation in setting security prices. It seems reasonable to assume that investors are concerned with real returns on securities. Since all uncertainty in the real return on a one-month bill is uncertainty about the change in the purchasing power of money during the month, one-month bills are the clear choice for studying how well the market absorbs information about inflation one month ahead. For the same reason, *n*-month bills are best for studying *n*-month predictions of inflation.

B. *The General Description of an Efficient Market*

Market efficiency requires that in setting the price of a one-month bill at t−1, the market correctly uses all available information to assess the distribution of $\tilde{\Delta}_t$. Formally, in an efficient market,

$$(6)\qquad f_m(\Delta_t \mid \phi^m_{t-1}) = f(\Delta_t \mid \phi_{t-1})$$

where ϕ_{t-1} is the set of information available at t−1, ϕ^m_{t-1} is the set of information used by the market, $f_m(\Delta_t \mid \phi^m_{t-1})$ is the market assessed density function for $\tilde{\Delta}_t$, and $f(\Delta_t \mid \phi_{t-t})$ is the true density function implied by ϕ_{t-1}.

When the market sets the equilibrium price of a one-month bill at t−1, R_t is also set. Given the relationship among $\tilde{r}_t$, R_t, and $\tilde{\Delta}_t$ of (5), the market's assessed distribution for $\tilde{r}_t$ is implied by R_t and its assessed distribution for $\tilde{\Delta}_t$. If (6) holds, then the market's assessed distribution for $\tilde{r}_t$ is the true distribution

$$(7)\qquad f_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t) = f(\tilde{r}_t \mid \phi_{t-1}, R_t)$$

In short, if the market is efficient, then in setting the nominal price of a one-month bill at t−1, it correctly uses all available information to assess the distribution of $\tilde{\Delta}_t$. In this sense v_{t-1} fully reflects all available information about $\tilde{\Delta}_t$. Since an equilibrium value of v_{t-1} implies an equilibrium value of R_t, the one-month nominal rate of interest set in the market at t−1 likewise fully reflects all available information about $\tilde{\Delta}_t$. Finally, when an efficient market sets R_t, the distribution of the real return $\tilde{r}_t$ that it perceives is the true distribution.

C. *A Simple Model of Market Equilibrium*

The preceding specification of market efficiency is so general that it is not testable. Since we cannot observe $f_m(\Delta_t \mid \phi^m_{t-1})$, we cannot determine whether (6) holds, and so we cannot determine whether the the bill market is efficient. What the model lacks is a more detailed specification of the link between $f_m(\Delta_t \mid \phi^m_{t-1})$ and v_{t-1}; that is, we must specify in more detail how the equilibrium price of a bill at t−1 is related to the market-assessed distribution of $\tilde{\Delta}_t$. This is a common feature of tests of market efficiency. A test of efficiency must be based on a model of equilibrium, and any test is simultaneously a test of efficiency and of the assumed model of equilibrium.

The first assumption of the model of bill market equilibrium is that in their decisions with respect to one-month bills, the primary concern of investors is the distribution of the real return on a bill. A market equilibrium depends visibly on a market-clearing value of the nominal price v_{t-1}, but it is assumed that what causes investors to demand the outstanding supply of bills is the implied "equilibrium distribution" of the real return. Testable propositions about market efficiency then require propositions about the characteristics of the market assessed distribution $f_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t)$ that results from an equilibrium price v_{t-1} at t−1. As is common in tests of market efficiency, we concentrate on the mean of the distribution, and the proposition about $E_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t)$ is that for all t and ϕ^m_{t-1},

$$(8)\qquad E_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t) = E(\tilde{r})$$

Thus the model of bill market equilibrium is the statement that each month the market sets the price of a one-month bill so that it perceives the expected real return on the bill to be $E(\tilde{r})$. In short, the equilibrium expected real return on a one-month bill is assumed to be constant through time.

II. Testable Implications of Market Efficiency When the Equilibrium Expected Real Return Is Constant Through Time

A. *The Real Return*

In an efficient market (7) holds, and (7) implies

$$(9)\qquad E_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t) = E(\tilde{r}_t \mid \phi_{t-1}, R_t)$$

If market equilibrium is characterized by (8), then with (9) we have

$$(10)\qquad E(\tilde{r}_t \mid \phi_{t-1}, R_t) = E(\tilde{r})$$

Thus at any time t−1 the market sets the price of a one-month bill so that its assessment of the expected real return is the constant $E(\tilde{r})$. Since an efficient market correctly uses all available information, $E(\tilde{r})$ is also the true expected real return on the bill.

The general testable implication of this combination of market efficiency with a model of market equilibrium is that there is no way to use ϕ_{t-1}, the set of information available at t−1, or any subset of ϕ_{t-1}, as the basis of a correct assessment of the expected real return on a one-month bill which is other than $E(\tilde{r})$. One subset of ϕ_{t-1} is the time-series of past real returns. If (10) holds,

$$E(\tilde{r}_t \mid r_{t-1}, r_{t-2}, \ldots) = E(\tilde{r}) \tag{11}$$

That is, there is no way to use the time-series of past real returns as the basis of a correct assessment of the expected real return which is other than $E(\tilde{r})$. If (11) holds, the autocorrelations of $\tilde{r}_t$ for all lags are equal to zero, so that sample autocorrelations provide tests of (11).

Sample autocorrelations of $\tilde{r}_t$ are presented later, but it is well to make one point now. The autocorrelations are joint tests of market efficiency and of the model for the equilibrium expected real return. Thus nonzero autocorrelations of $\tilde{r}_t$ are consistent with a world where the equilibrium expected real return is constant and the market is inefficient, but nonzero autocorrelations are also consistent with a world where the market is efficient and equilibrium expected real returns change through time as a function of the sequence of past real returns. Market efficiency in no way rules out such behavior of the equilibrium expected return.

B. *The Nominal Interest Rate as a Predictor of Inflation*

There are tests that distinguish better between the hypothesis that the market is efficient and the hypothesis that the expected real return is constant through time. From (5), the relationship between the market's expectation of the rate of change in purchasing power, the nominal rate of interest, and the market's expectation of the real return is

$$E_m(\tilde{\Delta}_t \mid \phi^m_{t-1}) = E_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t) - R_t \tag{12}$$

If the expected real return is the constant $E(\tilde{r})$, then (12) becomes

$$E_m(\tilde{\Delta}_t \mid \phi^m_{t-1}) = E(\tilde{r}) - R_t \tag{13}$$

If the market is also efficient,

$$E(\tilde{\Delta}_t \mid \phi_{t-1}) = E(\tilde{r}) - R_t \tag{14}$$

Thus a constant expected real return implies that all variation through time in the nominal rate R_t is a direct reflection of variation in the market's assessment of the expected value of $\tilde{\Delta}_t$. If the market is also efficient, then all variation in R_t mirrors variation in the best possible assessment of the expected value of $\tilde{\Delta}_t$. Moreover, once R_t is set at time t−1, the details of ϕ_{t-1}, the information that an efficient market uses to assess the expected value of $\tilde{\Delta}_t$, become irrelevant. The information in ϕ_{t-1} is summarized completely in the value of R_t. In this sense, the nominal rate R_t observed at t−1 is the best possible predictor of the rate of inflation from t−1 to t.

To test these propositions, it is convenient to introduce a new class of models of market equilibrium that includes (8) as a special case. Suppose that at any time t−1 the market always sets the price of a one-month bill so that it perceives the expected real return to be

$$E_m(\tilde{r}_t \mid \phi^m_{t-1}, R_t) = \alpha_0 + \gamma R_t \tag{15}$$

If the market is also efficient, we have

$$E(\tilde{r}_t \mid \phi_{t-1}, R_t) = \alpha_0 + \gamma R_t \tag{16}$$

With (5), (15) and (16) imply that

$$E_m(\tilde{\Delta}_t \mid \phi^m_{t-1}) = \alpha_0 + \alpha_1 R_t, \quad \alpha_1 = \gamma - 1 \tag{17}$$

$$E(\tilde{\Delta}_t \mid \phi_{t-1}) = \alpha_0 + \alpha_1 R_t, \quad \alpha_1 = \gamma - 1 \tag{18}$$

In the new model, γ is the proportion of the change in the nominal rate from one month to the next that reflects a change in the equilibrium expected real return, and $-\alpha_1 = 1 - \gamma$ is the proportion of the change in R_t that reflects a change in the expected value of $\tilde{\Delta}_t$. In the special case where the expected real return is constant through time, $\gamma=0$, $\alpha_1=-1$, and all variation in R_t mirrors variation in $E(\tilde{\Delta}_t|\phi_{t-1})$.

Estimates of α_0 and α_1 in (18) can be obtained by applying least squares to

$$\tilde{\Delta}_t = \alpha_0 + \alpha_1 R_t + \tilde{\epsilon}_t \tag{19}$$

If the coefficient estimates are inconsistent with the hypothesis that

$$\alpha_0 = E(\tilde{r}) \quad \text{and} \quad \alpha_1 = -1 \tag{20}$$

the model of a constant equilibrium expected real return is rejected. The more general interpretation of (15), that is, with unrestricted values of the coefficients, can then be taken as the model for the equilibrium expected real return, and other results from the estimates of (19) can be used to test market efficiency. Thus, like (14), (18) says that in an efficient market R_t summarizes all the information about the expected value of $\tilde{\Delta}_t$ which is in ϕ_{t-1}. For example, given R_t, the sequence of past values of the disturbance $\tilde{\epsilon}_t$ in (19) should be of no additional help in assessing the expected value of $\tilde{\Delta}_t$ which implies that the autocorrelations of the disturbance should be zero for all lags.

The approach is easily generalized to obtain other tests of (14). For example, one item of information available at $t-1$ is Δ_{t-1}. If periods of inflation or deflation tend to persist, then Δ_{t-1} is relevant information for assessing the expected value of $\tilde{\Delta}_t$. If the information in Δ_{t-1} is not correctly used by the market in setting R_t, then the coefficient α_2 in

$$\tilde{\Delta}_t = \alpha_0 + \alpha_1 R_t + \alpha_2 \Delta_{t-1} + \tilde{\epsilon}_t \tag{21}$$

is nonzero. On the other hand, if (14) holds, the market is efficient and the value of R_t set at $t-1$ summarizes all the information available about the expected value of $\tilde{\Delta}_t$, which includes any information in Δ_{t-1} and any information in the past values of $\tilde{\epsilon}_t$. Thus, in this case, $\alpha_2=0$ and the autocorrelations of the disturbance $\tilde{\epsilon}_t$ in (21) are zero for all lags. Moreover, if (14) holds, the expected real return is constant through time, so that the values of α_0 and α_1 in (21) are as in (20). All of these propositions are tested below with least squares estimates of (21).

C. *Reinterpretation of the Proposed Tests*

It is well to recognize that all of the tests of market efficiency are different ways to examine whether in assessing the expected value of $\tilde{\Delta}_t$, the market correctly uses any information in the past values $\Delta_{t-1}, \Delta_{t-2}, \ldots$. The point is obvious with respect to tests based on the coefficient α_2 in (21). The argument is also direct for the autocorrelations of the disturbances $\tilde{\epsilon}_t$ in (19) and (21). The disturbance $\tilde{\epsilon}_t$ in (19) is the deviation of $\tilde{\Delta}_t$ from the market's assessment of its conditional expected value, when $E_m(\tilde{\Delta}_t|\phi^m_{t-1})$ is given by (17). The autocorrelations of $\tilde{\epsilon}_t$ tell us whether the past values of these deviations are used correctly by the market when it assesses the expected value of $\tilde{\Delta}_t$. Nonzero autocorrelations imply that the market is inefficient; one can improve on the market's assessment of the expected value of $\tilde{\Delta}_t$ by making correct use of information in past values of Δ_t. Likewise the disturbance $\tilde{\epsilon}_t$ in (21) is the deviation of $\tilde{\Delta}_t$ from its conditional expected value when the latter is allowed to be a function of Δ_{t-1} as well as of R_t. Finally, if the equilibrium expected real return is constant through time, then the market's assessment of the expected value of $\tilde{\Delta}_t$ is described by (13). From (5) it then follows that

$$\tilde{r}_t - E(\tilde{r}) = \tilde{\Delta}_t + R_t - E(\tilde{r}) \tag{22a}$$

$$= \tilde{\Delta}_t - E_m(\tilde{\Delta}_t \mid \phi^m_{t-1}) \tag{22b}$$

Thus, the deviation of $\tilde{r}_t$ from its expected value is the deviation of $\tilde{\Delta}_t$ from the market's assessment of its expected value, when the latter is described by (13). Tests of market efficiency based on the autocorrelations of $\tilde{r}_t$, like all the other proposed tests, are concerned with whether the market correctly uses any information in the time-series of past values, Δ_{t-1}, Δ_{t-2}, . . . , when it assesses $E_m(\tilde{\Delta}_t | \phi^m_{t-1})$ on which the nominal rate R_t is then based. Any such test must assume some model of market equilibrium, that is, some proposition about the equilibrium expected real return $E_m(\tilde{r}_t | \phi^m_{t-1})$, which in turn implies some proposition about $E_m(\tilde{\Delta}_t | \phi^m_{t-1})$, and this is where the tests differ.

There is, however, no need to apologize for the fact that the tests of market efficiency concentrate on the reaction of the market to information in the time-series of past rates of change in the purchasing power of money. Beginning with the pioneering work of Fisher, researchers in this area have long contended, and the results below substantiate the claim, that past rates of inflation are important information for assessing future rates. Moreover, previous work almost uniformly suggests that the market is inefficient; in assessing expected future rates of inflation, much of the information in past rates is apparently ignored. This conclusion, if true, indicates a serious failing of a free market. The value of a market is in providing accurate signals for resource allocation, which means setting prices that more or less fully reflect available information. If the market ignores the information from so obvious a source as past inflation rates, its effectiveness is seriously questioned. The issue deserves further study.

III. The Data

The one-month nominal rate of interest R_t used in the tests is the return from the end of month t−1 to the end of month t on the Treasury Bill that matures closest to the end of month t. The data are from the quote sheets of Salomon Brothers. In computing R_t from (1), the average of the bid and asked prices at the end of month t−1 is used for the nominal price v_{t-1}. The Bureau of Labor Statistics Consumer Price Index (*CPI*) is used to estimate Δ_t, the rate of change in the purchasing power of money from the end of month t−1 to the end of month t. The use of any index to measure the level of prices of consumption goods can be questioned. There is, however, no need to speculate about the effects of shortcomings of the data on the tests. If the results of the tests seem meaningful, the data are probably adequate.

The tests cover the period from January 1953 through July 1971. Tests for periods prior to 1953 would be meaningless. First, during World War II and up to the Treasury-Federal Reserve Accord of 1951, interest rates on Treasury Bills were pegged by the government. In effect, a rich and obstinate investor saw to it that Treasury Bill rates did not adjust to predictable changes in inflation rates. Second, at the beginning of 1953 there was a substantial upgrading of the *CPI*.[3] The number of items in the Index increased substantially, and monthly sampling of major items became the general rule. For tests of market efficiency based on monthly data, monthly sampling of major items in the *CPI* is critical. Sampling items less frequently than monthly, the general rule prior to 1953, means that some of the price changes for month t show up in the Index in months subsequent to t. Since nominal prices of goods tend to move together, spreading price changes for month t into following months creates spurious positive autocorrelation in monthly changes in the Index. This gives the appearance that there is more information about future inflation rates in past inflation rates than is really the case. Since the spurious component of the information in measured inflation rates is not easily isolated, test of market efficiency on pre-

---

[3] See ch. 10 of the *BLS* reference.

1953 data would be difficult to interpret.

The values of the *CPI* from August 1971 to the present (mid-1974) are also suspect. During this period the Nixon Administration made a series of attempts to fix prices. The controls were effective in creating "shortages" of some important goods (who can forget the gas queues of the winter of 1973–74?), so that for this period there are nontrivial differences between the observed values of the *CPI* and the true costs of goods to consumers. For this reason, the tests concentrate on the "clean" precontrols period January 1953 to July 1971.

IV. Results for One-Month Bills

Table 1 shows sample autocorrelations $\hat{\rho}_\tau$ of Δ_t for lags τ of from one to twelve months. The table also shows sample means and standard deviations of Δ_t, and

$$\sigma(\hat{\rho}_1) = 1/(T-1)^{1/2} \tag{23}$$

where $T-1$ is the number of observations used to compute $\hat{\rho}_1$, and $\sigma(\hat{\rho}_1)$ is the approximate standard error of $\hat{\rho}_1$ under the hypothesis that the true autocorrelation is zero. Table 2 shows sample autocorrelations and other statistics for the real return $\tilde{r}_t$. Although, for simplicity, the development of the theory is in terms of the approximation given by (5), the exact expression (3) is used to compute $\tilde{r}_t$ in the empirical work.

Table 3 shows summary statistics for the estimated version of (19). In addition to the least squares regression coefficient estimates a_0 and a_1, the table shows the sample standard errors of the estimates $s(a_0)$ and $s(a_1)$; the coefficient of determination, adjusted for degrees of freedom; $s(e)$, the standard deviation of the residuals; and the first three residual autocorrelations, $\hat{\rho}_1(e)$, $\hat{\rho}_2(e)$, and $\hat{\rho}_3(e)$. Table 4 shows similar summary statistics for the estimated version of (21).

A. *The Information in Past Inflation Rates*

The market efficiency hypothesis to be tested is that the one-month nominal interest rate R_t set in the market at the end of month t−1 is based on correct utilization of all the information about the expected value of $\tilde{\Delta}_t$, which is in the time-series of past values Δ_{t-1}, Δ_{t-2}, ... The hypothesis is only meaningful, however, if past rates of change in purchasing power do indeed have information about the expected future rate of change. The predominance

of large estimated autocorrelations of Δ_t in Table 1 indicates that this is the case.

In fact, especially for the longer periods 1/53–7/71 and 8/64–7/71, the sample autocorrelations of Δ_t for different lags are similar in size with individual estimates in the neighborhood of .30. This finding is discussed later when the behavior through time of Δ_t is studied in more detail.

B. *Market Efficiency*

Given that the equilibrium expected real return is constant through time, the market efficiency hypothesis says that the autocorrelations of the real return $\tilde{r}_t$ are zero for all lags. The sample autocorrelations of r_t in Table 2 are close to zero. Recall from (5) that the real return $\tilde{r}_t$ is approximately the rate of change in purchasing power Δ_t plus the nominal interest rate R_t. The evidence from the sample autocorrelations of Δ_t and r_t in Tables 1 and 2 is that adding R_t to Δ_t brings the substantial autocorrelations of Δ_t down to values close to zero. This is consistent with the hypothesis that R_t, the nominal rate set at $t-1$, summarizes completely the information about the expected value of $\tilde{\Delta}_t$ which is in the time-series of past values, $\Delta_{t-1}, \Delta_{t-2}, \ldots$.

Tables 3 and 4 give further support to the market efficiency hypothesis. When applied to (21), the hypothesis says that α_2, the coefficient of Δ_{t-1}, is zero, and the autocorrelations of the disturbance $\tilde{\epsilon}_t$ are likewise zero for all lags. The residual autocorrelations in Table 4 are close to zero. The values of a_2, the sample estimates of α_2 in (21), are also small and always less than two standard errors from zero. When applied to (19), the market efficiency hypothesis is again that the autocorrelations of the disturbance $\tilde{\epsilon}_t$ should be zero. The residual autocorrelations in Table 3 are close to zero. Moreover, comparing the results for the estimated versions of (19) and (21) in Tables 3 and 4 shows that dropping Δ_{t-1} from the model has almost no effect on the coefficients of determination, which is consistent with the implication of market efficiency that the value of R_t set at time $t-1$ summarizes any information in Δ_{t-1} about the expected value of $\tilde{\Delta}_t$.

Closer inspection of the tables seems to

TABLE 4—REGRESSION TESTS ON ONE-MONTH BILLS

8/64–7/71	.00073	−.89	.14	.00084	.24	.11	.24	.00164	−.04	.05	−.01

provide slight evidence against market efficiency. Except for the 3/59–7/64 period, the first-order sample autocorrelations of r_t, though small, are nevertheless all positive. The estimated regression coefficients a_2 of Δ_{t-1} in Table 4 are likewise small but generally positive, as are the first-order residual autocorrelations in Table 3. It is well to note, however, that even after the upgrading of the *CPI* in 1953, there are some items whose prices are sampled less frequently than monthly; and items that are sampled monthly are not sampled at the same time during the month. Again, since prices of goods tend to move together, these quirks of the sampling process induce spurious positive autocorrelation in measured rates of change in purchasing power. Since an efficient market does not react to "information" that is recognizably spurious, the small apparent discrepancies from efficiency provide more "reasonable" evidence in favor of the efficiency hypothesis than if the data suggested that the hypothesis does perfectly well.

C. *The Expected Real Return*

The evidence is also consistent with the hypothesis that the expected real return on a one-month bill is constant during the 1953–71 period. First, the sample autocorrelations of the real return $\tilde{r}_t$ are joint tests of the hypotheses that the market is efficient and that the expected real return is constant through time. Since the sample autocorrelations of r_t in Table 2 are close to zero, the evidence is consistent with a world where both hypotheses are valid.

The regression coefficient estimates for (19) and (21) in Tables 3 and 4 are, however, more direct evidence on the hypothesis that the expected value of $\tilde{r}_t$ is constant. The hypothesis implies that in (19) and (21), the intercept α_0 is the constant expected real return $E(\tilde{r})$ and the coefficient α_1 of R_t is -1.0. The coefficient estimates a_1 of α_1 in (19) and (21) are always well within two standard errors of -1.0. And statistical considerations aside, the estimate $a_1=-.98$ for (19) for the overall period 1/53–7/71 is impressively close to -1.0. Given estimates a_1 of α_1 in (19) and (21) that are close to -1.0, and given the earlier observation that the estimates a_2 of α_2 in (21) are close to zero, equation (5) and the least squares formulas guarantee that the intercept estimates a_0 for (19) and (21) in Tables 3 and 4 are close to the sample means of the real return in Table 2.

Finally, the sample autocorrelations of r_t in Table 2 and the regression coefficient estimates a_0 and a_1 in Tables 3 and 4 are consistent with the world of equation (13) where the equilibrium expected real return is constant and all variation through time in the nominal interest rate R_t mirrors variation in the market's assessment of the expected value of $\tilde{\Delta}_t$. There is, however, another interesting way to check this conclusion. From the discussion of (22) it follows that the standard deviation of the real return $\tilde{r}_t$ is the standard deviation of the disturbance $\tilde{\epsilon}_t$ in (19) when the coefficients α_0 and α_1 in (19) are constrained to have the values $\alpha_0=E(r)$ and $\alpha_1=-1.0$ that are appropriate under the hypothesis that the expected real return is constant through time. If this hypothesis is incorrect, letting the data choose values of α_0 and α_1, as in Table 3, should produce lower estimates of the disturbance variance than when the values of the coefficients are constrained. But the results indicate that, especially for the longer periods, not only are the values of $s(r)$ in Table 2 almost identical to the values of $s(e)$ in Table 3, but the sample autocorrelations of r_t and e_t are almost identical. In short, the hypothesis that the expected real return is constant fits the data so well that the residuals from the estimated version of (19) are more or less identical to the deviations of $\tilde{r}_t$ from its sample mean.

V. The Behavior of $\tilde{\Delta}_t$

The results allow some interesting insights into the behavior through time of $\tilde{\Delta}_t$. The rate of change in purchasing power can always be written as

$$\tilde{\Delta}_t = E(\tilde{\Delta}_t \mid \phi_{t-1}) + \tilde{\epsilon}_t \tag{24}$$

Since the evidence is consistent with the hypothesis that the expected real return is constant through time, we can substitute (14) into (24) to get

$$\tilde{\Delta}_t = E(\tilde{r}) - R_t + \tilde{\epsilon}_t \tag{25}$$

The conclusion drawn from the residual autocorrelations in Table 3 and the sample autocorrelations of $\tilde{r}_t$ in Table 2 is that the disturbance $\tilde{\epsilon}_t$ in (25) is uncorrelated through time. The time-series of past values of $\tilde{\epsilon}_t$ is no real help in predicting the next value. Quite the opposite sort of behavior characterizes the expected value of $\tilde{\Delta}_t$ in (24). Since, as stated in (25), variation in R_t through time mirrors variation in the expected value of $\tilde{\Delta}_t$, the time-series properties of R_t are the time-series properties of $E(\tilde{\Delta}_t \mid \phi_{t-1})$. For the 1/53–7/71 period, the first four sample autocorrelations of R_t are all in excess of .93, and only one of the first twenty-four is less than .9. Sample autocorrelations close to 1.0 are consistent with the representation of R_t as a random walk. Thus in contrast with the evidence for the disturbance $\tilde{\epsilon}_t$ in (24), the autocorrelations of R_t indicate that there is much persistence through time in the level of R_t and thus in the level of $E(\tilde{\Delta}_t \mid \phi_{t-1})$. The time-series of past values of R_t has substantial information about future values.

This discussion helps explain the behavior of the sample autocorrelations of $\tilde{\Delta}_t$ in Table 1. As stated in (24), $\tilde{\Delta}_t$ has two components. One component of $\tilde{\Delta}_t$, its expected value, behaves like a random walk. The other component of $\tilde{\Delta}_t$, the disturbance $\tilde{\epsilon}_t$, is essentially random noise. The autocorrelations of its expected value cause the autocorrelations of $\tilde{\Delta}_t$ to likewise have approximately the same magnitude for different lags. The uncorrelated disturbance $\tilde{\epsilon}_t$, however, causes the autocorrelations of $\tilde{\Delta}_t$, unlike those of R_t, to be far below 1.0.

The sample autocorrelations of R_t suggest that the expected value of $\tilde{\Delta}_t$ behaves through time much like a random walk. The sample autocorrelations of the month-to-month changes in R_t, shown in Table 5, suggest, however, that we can improve on this description of the behavior of $E(\tilde{\Delta}_t \mid \phi_{t-1})$. For example, the first-order autocorrelations of $R_t - R_{t-1}$ are consistently negative. From the first-order autocorrelations for the longer periods, the change in R_t might reasonably be represented as

$$\tilde{R}_{t+1} - R_t = -.25(R_t - R_{t-1}) + \tilde{\eta}_t \tag{26}$$

Thus the process that generates the nominal rate is no longer just a random walk. The process is slightly regressive so that on average the change in the expected inflation rate from one month to the next reverses itself by about 25 percent.

VI. Results for Bills with Longer Maturities

The presentation of theory and tests of bill market efficiency has concentrated so far on one-month bills and one-month rates of change in the purchasing power of money. As far as the theory is concerned, the interval of time over which the variables are measured is arbitrary. In testing the theory, the fact that the *CPI* is only reported monthly limits us to tests based on intervals that cover an integral number of months. Tests are presented now for one- to six-month intervals. Thus, in these tests the interval from $t-1$ to t is one, or two, . . . , or six months; R_t is the sure one-, or two-, . . . , or six-month nominal rate of interest from $t-1$ to t on a bill with one, or two, . . . , or six months to maturity at $t-1$; and the real return $\tilde{r}_t$ and the rate of change in the purchasing power of money $\tilde{\Delta}_t$ are likewise measured for nonoverlapping one- to six-month intervals.

Since the theory and tests are the same for bills of all maturities, the market efficiency hypothesis is that in setting the nominal rate R_t at time $t-1$, the market correctly uses any information about the expected value of $\tilde{\Delta}_t$ which is in the time-series of past values $\Delta_{t-1}, \Delta_{t-2}, \ldots$. The model of market equilibrium on which the tests are based is the assumption that the expected real returns on bills with one to six months to maturity are constant through time. The tests of these propositions are in Tables 6 to 9, and the tests are the same as those for one-month bills in Tables 1 to 4. Results for the one- to three-month versions of the variables are shown for the 1/53–7/71 and 3/59–7/71 periods. Since the data for four- to six-month bills are only available beginning in March 1959, results for the four- to six-month versions of the variables are only shown for the 3/59–7/71 period.

Implicit in the tests of market efficiency is the assumption that past rates of change in purchasing power have information about expected future rates of change. The autocorrelations of Δ_t in Table 6 support this assumption. The autocorrelations are large for all six intervals used to measure Δ_t. But consistent with the hypotheses that the market is efficient and that the equilibrium expected real returns on bills with different maturities are constant through time, the autocorrelations of the real returns shown in Table 7 are close to zero. Remember from (5) that the n-month real return on an n-month bill is approximately the n-month rate of change in purchasing power plus the n-month nominal return on the bill. Thus the evidence from the autocorrelations of Δ_t and r_t in Tables 6 and 7 is that when R_t is added to Δ_t, the substantial autocorrelations of Δ_t drop to values close to zero. This is consistent with a world where R_t, the n-month nominal rate set at $t-1$, summarizes all the information about the expected value of the rate of change in purchasing power over the n months from $t-1$ to t which is in the time-series of past rates of changes in purchasing power.

The model gets further support from the regression tests in Table 8. Consistent with the hypothesis that expected real returns are constant through time, the estimates a_1 of α_1 in (19) in Table 8 are all impressively close to -1.0. Consistent with the hypothesis that the market is efficient, the residual autocorrelations in Table 8 are close to zero for bills of all maturities.

The only hint of evidence against the model is in the estimates of (21) for five- and six-month bills in Table 9. As predicted by the model, the values of a_1 and a_2 for one- to four-month bills are close to -1.0 and 0.0, and the residual autocorrelations are close to 0.0. For the five- and six-month bills, however, the values of a_1 are rather far from -1.0 and the values of a_2

TABLE 6—AUTOCORRELATIONS OF Δ_t: ONE- TO-SIX-MONTH INTERVALS

are rather far from 0.0. In conducting so many different tests for so many different bills, however, some results are likely to turn out badly even though the model is a valid approximation to the world. This argument gains force from the fact that the autocorrelations of the real returns in Table 7 and the estimates of (19) in Table 8 do not produce evidence for five- and six-month bills that contradicts the model.

VII. Interest Rates as Predictors of Inflation: Comparisons with the Results of Others

In a world where equilibrium expected real returns on bills are constant through

time, then, aside from the additive constant $E(\tilde{r})$ in (13), the nominal rate R_t set at time t−1 is in effect the market's prediction of the rate of change in purchasing power from t−1 to t. The coefficients of determination in Table 8 indicate that variation through time in these predictions accounts for 30 percent of the variance of subsequently observed values of Δ_t in the case of one-month bills, and the proportion of the sample variance of Δ_t accounted for by R_t increases to about 65 percent for five- and six-month bills. Thus, nominal interest rates observed at t−1 contain nontrivial information about the rate of change in purchasing power from t−1 to t. Moreover, the evidence on market efficiency suggests that the market's prediction of $\tilde{\Delta}_t$ is the best that can be made on the basis of information available at time t−1; or, more precisely, it is the best that can be done on the basis of information in past rates of change in purchasing power.

As noted earlier, the results reported here differ substantially from those of the rest of the literature on interest rates and inflation. In line with the early work of Fisher, the almost universal finding in other studies is that the market does not perform efficiently in predicting inflation. But the earlier studies, including, of course, Fisher's, are based primarily on pre-1953 data, and the negative results on market efficiency may to a large extent just reflect poor commodity price data. By

the same token, the success of the tests reported here is probably to a nonnegligible extent a consequence of the availability of good data beginning in 1953.

Poor commodity price data also probably explain why the empirical literature is replete with evidence in support of the so-called Gibson Paradox—the proposition that there is a positive relationship between the nominal interest rate and the level of commodity prices, rather than the relationship between the interest rate and the rate of change in prices posited by Fisher.[4] With a poor price index, the Fisherian relationship between the nominal interest rate and the true inflation rate can be obscured by noise and by spurious autocorrelation in measured inflation rates. But over long periods of time—and the Gibson Paradox is usually posited as a long-run phenomenon—even a poor index picks up general movements in prices. Thus if inflations and deflations tend to persist (an implication of the evidence presented here that $E(\tilde{\Delta}_t|\phi_{t-1})$ is close to a random walk), there may well appear to be a relationship between the level of interest rates and the measured level of prices, which merely reflects the more fundamental Fisherian relationship between the interest rate and the rate of change of prices that is obscured by poor data. In this study, which is based on the relatively clean data of the 1953–71 period, the Fisherian relationship shows up clearly.

VIII. Conclusions

The two major conclusions of the paper are as follows. First, during the 1953–71 period, the bond market seems to be efficient in the sense that in setting one- to six-month nominal rates of interest, the market correctly uses all the information about future inflation rates that is in time-series of past inflation rates. Second, one cannot reject the hypothesis that equilibrium expected real returns on one- to six-month bills are constant during the period. When combined with the conclusion that the market is efficient, this means that one also cannot reject the hypothesis that all variation through time in one- to six-month nominal rates of interest mirrors variation in correctly assessed one- to six-month expected rates of change in purchasing power.

The Theory of "Screening," Education, and the Distribution of Income

By JOSEPH E. STIGLITZ*

One of the most important kinds of information concerns the *qualities* of a factor or a commodity. We know that there are important differences among individuals, among bonds, among equities, among brands of automobiles. The identification of these qualities we call *screening*, and devices that sort our *commodities* (individuals) according to their qualities we call *screening devices* (for example, egg sorters).

This paper focuses on the labelling of individuals, on the economic costs and benefits of labelling, the institutions that provide it, and the determination of the equilibrium amount of screening under various institutional arrangements.

Economists have traditionally argued that because of the problem of appropriability in a market context, too few resources will be allocated to obtaining "information." This is not the case with the information provided by screening processes: individuals who can be labelled as "more productive" are able thereby to obtain a higher wage, partly, however, at the expense of others. Thus, by its very nature, screening information has important effects on the distribution of income.

The basic argument of this paper is that economies with imperfect information with respect to qualities of individuals differ in fundamental ways from economies with perfect information. There may be, for instance, multiple equilibria in which one of the equilibria is Pareto inferior to another; the Pareto inferior equilibrium may involve either too much or too little screening, or it may entail the wrong kind of screening. On the other hand, there may be situations where there exists no equilibrium.

The paper is divided into two parts. In

The research described in this paper was conducted in part while I was a Research Fellow at the Institute for Development Studies, University of Nairobi, 1969–71 under a grant from the Rockefeller Foundation. Financial support from the Ford and National Science Foundation is also gratefully acknowledged. I am indebted to Gary Fields, Michael Rothschild, Michael Spence, and to participants at seminars at Yale, Pennsylvania, Chicago, Queens, Wesleyan, and Princeton at which earlier versions of this paper were presented, for helpful conversations and comments.

The idea that education serves as a screening device and that as a result the allocation of resources to education may not be optimal is, of course, an old one. (See, for instance, Hull and Peters (1969) and Young (1958).) More recently, Thurow, Fields, Akerlof (1973), Spence, and Arrow (1973) have discussed education as a screening device. The first two papers assume a disequilibrium in the labor market (i.e., wages of any group of individuals need not equal the mean marginal product of the group); none of the papers, with the exception of Fields, appears to contain a completely articulated theory of the equilibrium of the system (the "supply" of education), and without a theory of the determination of the screening mechanism, it is difficult to make welfare economic evaluations of the system. For a more extensive discussion of this point, see Rothschild and Stiglitz (1973a). Several of the results are closely related to those obtained independently by Akerlof (1973), Spence, and Arrow (1973). As we show below, the presumption that these papers attempt to establish, that there is too much screening, is not necessarily valid. Various aspects of the theory of screening have recently been the subject of extensive discussion in other areas besides those of the capital market and education referred to earlier: in insurance markets (Rothschild and Stiglitz (1973a)), in labor markets (Salop and Salop (1972)), in discrimination (Arrow (1972), Phelps, Stiglitz (1973, 1974)), and in product markets (Salop (1973)). See also Akerlof's (1970) seminal work on the theory of lemons.

Section I, I develop, partly by means of a number of examples, the central aspects of the theory of screening. Section II is devoted to an analysis of the implications of screening for the allocation of resources to education.

I. The Theory of Screening

A. *The Benefits and Costs of Screening: Private Returns*

We begin with the simplest possible example involving screening. All our later examples (and the examples of George Akerlof (1973), Kenneth Arrow (1973), Michael Spence, J. K. Salop and S. C. Salop, and Michael Rothschild and the author (1973a)) can be thought of as elaborations—on the screening mechanism, the production technology, etc.—of this example.

Consider a population in which individuals can be described (at least for economic purposes) by a single characteristic, which we denote by θ, and which is proportional to the individual's productivity p:

$$p = m\theta$$

(That is, an individual of type θ_2 can do in an hour what a worker of type θ_1 can do in θ_1/θ_2 hours.) The variable p can be interpreted as the individual's marginal product. We choose our units so that $m=1$. The fraction of the population that is of type θ is given by $h(\theta)$.

Assume that the individual knows his ability but the market does not, and in the absence of any information treats all individuals identically. Firms are risk neutral, and act competitively. Assume moreover that the individual is assigned to an assembly line, and on that assembly line it is impossible to tell the productivity of any single individual without prohibitively costly examination. The output per man of the assembly line is proportional to the average value of θ for those working on the assembly line, and there are no other factors of production.

Under these assumptions, a worker will receive a wage equal to the mean value of those with whom he is grouped. If individuals with higher θ can be identified, they will receive a higher wage. They thus have an economic incentive to be identified.

Consider a case where there are only two groups, denoted by θ_1 and θ_2, $\theta_1 > \theta_2$, and which we refer to as the more able and less able, respectively. Assume there is a screening process which screens perfectly[1] and which costs c per individual screened, where

$$(1) \qquad \theta_1 - \theta_2 > c > \theta_1 - \bar{\theta}$$

$$(2) \qquad \bar{\theta} = \theta_1 h(\theta_1) + \theta_2(1 - h(\theta_1))$$

$$= \text{average value of } \theta$$

First we consider a case where the supply of labor by each individual is inelastic, so that with perfect knowledge, the first group would receive an income of θ_1 and the second an income of θ_2. These are best thought to be lifetime incomes, i.e., present discounted values of wage streams.

We now establish that there are two equilibria:

(a) *The no-screening equilibrium.* Since no differentiation is made among individuals, they will all receive the same income, equal to the mean productivity of the population, $\bar{\theta}$. To see that this is an equilibrium observe that it does not pay any individual, in particular, it does not pay the more able individual, to be screened. For with screening, he would obtain a gross income of θ_1, from which we must subtract the cost of screening to obtain net income, $\theta_1 - c$, and by (1), this is less than the income he would have received in the absence of screening, $\bar{\theta}$.

---

[1] Implicitly, we assume that the technology of screening is such that if less than c is spent, there is no screening, i.e., labels are assigned randomly.

(b) *The full-screening equilibrium.* The individuals of type θ_1 receive a gross income of θ_1, a net income of $\theta_1 - c$ (after paying for screening costs); individuals of type θ_2 receive an income of θ_2. Since these individuals know that they are the less able, they do not pay for any screening. Clearly, it pays individuals of type 1 to pay for screening: By our assumptions, all individuals who are not screened are "lumped" together and receive the same wage, so an individual of type 1 who is not screened would have received an income of θ_2, which by (1) is less than his net income with screening.

This simple example illustrates four propositions concerning economies with screening:

1) *There may be multiple equilibria.*[2]

2) *Some of the equilibria are unambiguously Pareto inferior to other equilibria.* Note that in the full-screening equilibrium, both groups have lower net incomes than in the no-screening equilibrium: the first group has an income of $\theta_1 - c$, which by (1) is less than $\bar{\theta}$; the second group an income of θ_2 which is obviously less than $\bar{\theta}$.

3) In both equilibria, *the presence of the less able individuals lowers the net income of the more able;* in the absence of the second group the first group would have received a wage of θ_1; in the full-screening equilibrium, net income is $\theta_1 - c$, in the no-screening equilibrium it is $\bar{\theta}$. *Conversely, the presence of the more able may increase the income of the less able* (in the no-screening equilibrium, they receive an income of $\bar{\theta}$ rather than an income of θ_2), *but need not* (as in the full-screening equilibrium).

4) *If one of the functions of education is to screen individuals,* as we shall argue later, *social returns* (ignoring distributional effects) *differ from private returns.* The gross social return, in this example, is zero (since the only effects of screening are distributional), the net returns are negative (since there is a cost). But the private rate of return (in the screening equilibrium) to screening, for the more able, is clearly positive:

$$\frac{\theta_1 - \theta_2}{c} - 1$$

Many screening equilibria have the characteristic that some individuals are better off than they would be in the absence of screening, some individuals are worse off, but total net national output is lower. One might be inclined to conclude that such a screening equilibrium is not Pareto optimal, but one must be careful. Assume instead of (1),

$$(1') \qquad \theta_1 - \bar{\theta} > c$$

Then there would not exist a no-screening equilibrium, but the losses from screening to group 2 exceed the gains to group 1. Clearly, if we forbade screening, we could compensate the upper group and divide the costs of screening among the population to make everyone better off. Such an argument misses, however, the essential nature of screening: neither the government nor the private producing sector knows who are the more able without screening; hence, in this example, even though with screening net national output is lower than without it, the screening equilibrium is Pareto optimal in the sense that the redistributions which would be required to make "someone better off without making anyone worse off" than they were in the screening equilibrium, are not feasible in the absence of the screening itself.

---

[2] The multiplicity of equilibria noted here is different from the kind observed by Spence, which arises from an incomplete specification of the equilibrium conditions (or, alternatively, from a different notion of equilibrium than that employed here). (See Rothschild and the author.)

On the other hand, since the screening does lower net national output and increase the inequality of income, ***under any quasi-concave*** (equality preferring) ***social welfare function the screening equilibrium just described is socially undesirable*** (see Anthony Atkinson, Rothschild and the author (1973b)).

These examples illuminate the nature of the private returns to screening: the individual's capturing of his "ability rents" which in the absence of screening he shares with others. It has several special characteristics which are essential for the results: (i) The more able are better in every relevant sense than the less able. Since there is an unambiguous ranking of abilities, we call such screening ***hierarchical.*** (ii) Labor is inelastically supplied and there are no increases in production from sorting individuals. (iii) Individuals have perfect information about their own abilities. (iv) There is no method of on-the-job screening. (v) The screening is perfectly accurate. (vi) The information acquired is "general" information. General information is information about characteristics of an individual which affect his productivity in a wide variety of jobs; specific information concerns characteristics which affect his productivity in a specific firm, for example, his ability to operate a particular machine. (The distinction corresponds to Gary Becker's distinction between general and specific training. These are clearly polar cases; as with training, there is a continuum of degrees of specificity/generality of information.) In subsequent sections I shall show the results are dependent on these characteristics.

In the remainder of this section I consider the private returns to the acquisition of general hierarchical screening information by an individual who is fully informed of his own abilities. I shall argue that in a private economy, as a first approximation, the benefits of such information would accrue to and the costs of information would be borne by the individual as opposed to the firm.

To see this, consider an economy in which individuals did not provide information about themselves. The wage in competitive equilibrium would be equal to the mean marginal product of the workers, and all workers would receive the same wage. Now assume that some firm did research which detected which workers (or groups of workers) were more productive. If it were able to keep that information secret, it would be able to earn, as a return to obtaining that information, the difference between the marginal productivity of these workers and the average of the population as a whole. Thus, it would pay firms to do research to obtain this information, provided, of course, that the costs of obtaining the information were sufficiently low. If the information were to become ***public,*** however, the worker would receive the benefits of the information: other firms would bid for his service, until his wage rose to his marginal productivity.

There are thus two conflicts of interest: the worker wishes to have all such information public, the firm private; and to the extent that some of the return is captured by the worker, the firm will not allocate as much resources to obtaining information about the quality of the individual as the more able individuals would have liked.

We have so far established that the most able individuals have an economic interest in providing information about their capabilities. But the gain of the more productive workers may be at least partially at the expense of the less productive workers. It may be in the interests of the poorer workers for the information about who is the best worker not to be known. I shall now argue that if information were relatively costless, in a competitive economy everyone except the poorest (least capable) individual would have an economic interest in providing such information. For, assume the most able is able to provide information certifying to his abilities. The market would then, in equilibrium, pay the remaining workers their (now lower) mean marginal productivity. It would clearly pay, then, for the most able person of this group to have his ability certified. And the analysis proceeds, until information about the capabilities of all individuals except for the least capable is provided: but if we have sorted out all except for the least capable, we have also sorted out the least capable. This may be called the Walras Law of screening information.

Our basic argument can be summarized as follows: *since individuals are able to capture the returns to general information about their skills themselves, they are willing to spend resources to provide this information*—indeed, this is the only way they can fully capture their "ability rents"; and in a competitive economy, firms that allocate resources to obtaining general screening information about individuals will be unable to appropriate (most of) the returns.

There are some conditions under which even the most able may not be willing to pay for "general screening." (a) If there are self-employment opportunities where they can realize the same returns that they would have realized had they been accurately screened, any "underrated" individual would be self-employed. For most individuals, this is not a relevant possibility. (b) If individuals are perfectly certain of their ability, and if it is possible for their ability to be costlessly observed "on the job" then the individual would offer to absorb all the risk involved in hiring and training costs. There are obviously instances of this sort, individuals who persuade the employer to hire them at low wages until they can "prove themselves." But for many jobs, ascertaining abilities (productivities) on the job may be relatively costly; most individuals are not perfectly certain of their abilities, and the screening is far from perfectly accurate. (c) If individuals are very risk averse and not perfectly certain of their abilities, then they may prefer to be treated simply as average rather than to undertake the chance of being screened and labelled below average. Indeed, in the examples given above, screening increases the variance of the individual's income and reduces the mean (since there is a cost to screening) and so, in such a situation, a "completely uninformed" individual, that is, one who took as the subjective probability distribution of his abilities the distribution of abilities in the population, would never screen. But even if there is a social return to screening, uninformed individuals may not undertake it (see Section ID below).

B. *The Social Benefits from Screening*

The examples of the previous section explicitly assumed that there was no social return to screening; i.e., screening did not increase output, it just redistributed it. Here we discuss the two major categories of social returns.

1. *Tradeoffs.* In the absence of information, individuals receive a wage which differs from their true marginal product. Imperfect information acts just like a wage tax on the more able, a wage subsidy on the less able. Like all taxes, the "information wage tax" is distortionary in its effect on the consumption-leisure decision. If screening costs are small enough, so long as labor is elastically supplied, everyone can be made better off as a result of screening (provided we have the appropriate tax instruments).

(Often, however, the requisite redistributive taxes may not exist; in that case, some of the gains of the more able may be at the expense of the less able.)

Similarly, in choosing a job, an individual must trade off nonpecuniary returns with monetary returns, and if his wage does not correspond to his marginal productivity, he will not make the socially correct decision.

2. *Matching*. Even in the absence of nonpecuniary differences among firms, there is a "matching problem" in the individual's choice of jobs. It is widely recognized that individuals differ in the comparative skills with which they can perform different tasks (jobs) and the ease with which they learn different skills. If the typist has a comparative advantage in plumbing and the plumber a comparative advantage in typing, we can have both more typing and more plumbing if they "switch" jobs.

Educators often talk of the importance of matching an "educational program" to the needs and abilities of our students. The efficiency losses in attempting to train a moron to be an engineer are obvious; other kinds of education mismatching while not as obvious may in the aggregate be quite important.

Even within a given occupation, there are further matching problems. In many economic activities, individuals act together. What is easy to observe is the net output of the group, but this in turn is a complicated function of the different qualities of the individuals of the group. In the previous section, for instance, we considered an assembly line, the speed (output) of which depended simply on the average of the "productivities" of the individuals working on the line. It would perhaps have been more accurate to assume that it is a weighted average, with the individuals who are below average slowing the line down by more than those who are above average speed it up. In that case, total output would be greater if we had two assembly lines, one with slow workers, the other with fast workers, than if the workers were randomly mixed together. Although this example is based on the assumption that there are returns to group homogeneity, the argument that there exist social returns only requires that output depend in part on how individuals of different characteristics are grouped together.

A similar argument can be made with respect to man-machine interactions. Assume that there are different kinds of machines for producing a given level of output. There is a large training cost associated with the operation of each machine; training for one machine does not equip one for operating another. Each machine is optimally designed for an individual of a given ability (value of θ). Clearly there are social returns to knowing the individual's ability (θ). (If there were no training costs, we could quickly observe the output of the machine with any individual, and infer his ability from this.)

C. *Is There Too Little Screening?*

The previous two sections should make it clear that there is no clear correspondence between social and private returns to screening; in the absence of screening individuals are "grouped" together and so may either be subsidized by or be subsidizing other members of the group. Individuals capture the direct increase in their own productivity as a result of screening; but if, as a result of screening, individuals can be "better organized" (for example, by using more homogeneous assembly lines) then there is a kind of externality provided by the availability of information. Moreover, screening eliminates the subsidy which the individual will have been receiving (or extending to others with whom he is grouped). This is a private cost (return) which is not social. As a result of these two factors, there may be too little or too much screening. The following two examples illustrate important situations in which there is too little screening.

1. *Job-Matching Screening: Screening for Comparative Advantage.* Assume a type 1 worker has a productivity of θ_{1s} when assigned to a skilled job but a productivity of θ_{1u} when assigned to an unskilled job. Type 2 workers have a zero productivity on the skilled job. We assume that type 2 workers are actually more productive at the unskilled job than the type 1 workers:

$$\theta_{1s} > \theta_2 > \theta_{1u} \tag{3a}$$

The productivity differentials are such, however, that with no screening, all workers are assigned to unskilled jobs. Let $\bar{\theta}_u$ be the mean wage with no screening in the unskilled jobs,

$$\bar{\theta}_u = h(\theta_1)\theta_{1u} + h(\theta_2)\theta_2$$

Then

$$\bar{\theta}_u > h(\theta_1)\theta_{1s} \tag{3b}$$

If screening costs are such that

$$\max(\theta_{1s} - \bar{\theta}_u, \theta_2 - \bar{\theta}_u) < c < \theta_{1s} - \theta_{1u} \tag{3c}$$

then equilibrium entails no screening; for if an individual of type 1 is screened, his net income is $\theta_{1s} - c$ which is less than his income on the unskilled job, and if an individual of type 2 is screened his net income is $\theta_2 - c < \bar{\theta}$ (again by (3c)). On the other hand, if

$$\max(\theta_2 - \bar{\theta}_u, \theta_{1s} - \theta_2) < c < \theta_{1s} - \bar{\theta}_u < \theta_{1s} - \theta_{1u} \tag{3d}$$

then equilibrium entails a fraction γ of type 1 individuals being screened, where

$$\frac{\theta_2 h(\theta_2) + (1-\gamma)\theta_{1u}h(\theta_1)}{h(\theta_2) + (1-\gamma)h(\theta_1)} = \theta_{1s} - c \tag{4}$$

It is clear that $0 < \gamma < 1$ (at $\gamma = 0$, the right-hand side of (4) exceeds the left-hand side; at $\gamma = 1$, the left-hand side of (4) exceeds the right-hand side). In both cases, net national income maximization entails $\gamma = 1$. Using (3c) and (3d) one can show that by having a subsidy for screening so the cost of screening is lowered to $\theta_{1s} - \theta_2$, financed by a lump sum tax, everyone can be made better off. *If type 1 workers are less productive in unskilled jobs than type 2 workers, there is too little screening.* The reason for this is that in the alternative occupation, the potentially skilled workers are in effect subsidized by the unskilled.

These results do not depend on the lack of complementarity between the two kinds of jobs. For instance, if

$$Q = F(\theta_{1s}\gamma, \theta_2 + (1-\gamma)\theta_{1u})$$

where Q is output and F is a constant return to scale production function, maximization of Q may entail less than full screening but the equilibrium level of screening will still be smaller than the optimal level.

2. *Information Externalities: Returns to Homogeneity.* Assume that the output per worker of the assembly line is of the form

$$\bar{\theta} - \beta\sigma^2 \tag{5}$$

where σ^2 is the variance of abilities on the assembly line. Moreover, assume that there is a fixed, large number of individuals working on the assembly line. Equation (5) embodies the notion that homogeneous work forces work more efficiently. Let σ_θ^2 be the expected variance on the assembly line drawn from an unscreened population, and assume

$$\theta_1 - \bar{\theta} < \theta_1 - \theta_2 < c < \theta_1 - \bar{\theta} + \beta\sigma_\theta^2 \tag{6}$$

Then the (unique) equilibrium involves no screening: with no screening, everyone receives $\bar{\theta} - \beta\sigma_\theta^2$. If a single individual were to buy screening, his income would be (approximately) $\theta_1-\beta\sigma_\theta^2-c$ (since the degree of heterogeneity of the labor force would be unaffected, we assume that the costs of heterogeneity are allocated uniformly over all individuals) which by (6) is less than $\bar{\theta}-\beta\sigma_\theta^2$. On the other hand, with full screening everyone is better off: the lower group receives $\theta_2>\bar{\theta}-\beta\sigma_\theta^2$ (again by (6)) and the upper group receives $\theta_1-c>\bar{\theta}-\beta\sigma^2$. *Although Pareto optimality requires full screening, the market equilibrium entails no screening.* To see that the full-screening situation cannot be sustained by a competitive market (assuming individuals have to pay for their own screening), observe that with full screening the net income of the first group is $\theta_1-c<\theta_2$, the net income of the lower group.

One might have thought that if $c<\beta\sigma_\theta^2$, it would pay firms to screen their workers if they do not screen themselves, since they would then obtain an average output of $\bar{\theta}$ rather than $\bar{\theta}-\beta\sigma_\theta^2$. But if the information about the outcome of screening could not be kept secret (for example, if the two types of assembly lines are different), then type 1 individuals would all be bid away, and so screening would be unprofitable. We assume the firm is aware of this and therefore would do no screening.

D. *Uninformed Individuals*

There is another reason besides the two presented in the previous section why there may not be screening even when it might be possible for everyone to be better off with screening: individuals are uninformed about their abilities and are risk averse. Assume, for instance, that labor is elastically supplied. Then it is possible to show that with the appropriate set of taxes, if the costs of screening are sufficiently small, everyone can be made better off both *ex ante* (expected utility before screening) and *ex post* than in the no-screening equilibrium, but if individuals are sufficiently risk averse, the only equilibrium will entail no screening. The source of "market failure" here is different from those discussed earlier: now the problem is the unobtainability of "ability" insurance, presumably largely because of difficulties with moral hazard.

In such a situation, there is still an incentive for the firm to obtain information about individuals; for if the firm can find individuals whose market wage is below their marginal productivity it can capture the difference between the two, if it can keep the information secret. If, as is often the case, this information cannot easily be kept secret, for example, if individuals of different abilities are assigned to different jobs (kinds of machines), then it would not pay any firm to do screening even if the firm were risk neutral. For other firms would bid away the more productive workers. The firm doing the research would not be able to capture the returns.

There is another problem in competitive economies with uninformed individuals: if two competing firms "discover" that a given individual's marginal product is greater than his wage, then they compete against each other; the individual's wage is bid up until it equals his marginal product, and neither firm is able to capture the returns from doing the research. For a more extended discussion of this point, see the author (1974c).

E. *On-the-Job Screening*

The previous analysis assumed that the screening and production activities were completely separated and there was no on-the-job screening. This is important for two reasons. First, with binding contracts (for the firm not to fire the unproductive, for the productive individuals not to quit), the equilibrium will always be Pareto optimal. For if it were not, any firm, by integrating the screening and production processes could make a pure profit: in effect there is nothing the government could do in these circumstances that an intelligent entrepreneur could not do. In fact, even though there is some on-the-job screening, considerable screening does occur in the educational system, and as long as that is the case, the problems we have detailed above remain. Secondly, on-the-job screening is likely to screen for somewhat different characteristics than, say, educational screening; the return to on-the-job screening is likely to depend on the amount of educational screening and conversely. In the absence of coordination of screening and production, *the equilibrium screening may well be Pareto inefficient,* as the following example illustrates.

Assume individuals are characterized by two characteristics, θ and ϕ, and their productivity is a function of θ and ϕ. (θ may be viewed as a characteristic screened for by the education system, ϕ is a characteristic screened for on the job.) For simplicity, we let $p=p(\theta, \phi)=\theta\phi$. We consider a population with four groups $(\theta_1\phi_1)$, $(\theta_2\phi_1)$, $(\theta_1\phi_2)$, $(\theta_2\phi_2)$, with $\phi_1>\phi_2$, $\theta_1>\theta_2$. Let $h(\theta_i, \theta_j)$ be the proportion of the population with characteristics θ_i and ϕ_j. Define

$$\bar{\theta}(\phi_i) \equiv \frac{\theta_1 h(\theta_1, \phi_i) + \theta_2 h(\theta_2, \phi_i)}{h(\theta_1, \phi_i) + h(\theta_2, \phi_i)}$$

and similarly define $\bar{\phi}(\theta_i)$. Let

$$\text{(7)} \quad \max\left[\phi_i(\theta_1 - \bar{\theta}(\phi_i)), \theta_i(\phi_1 - \bar{\phi}(\theta_i))\right] < c_\theta < c_\phi < \theta_1\phi_1 - \sum_i \sum_j \theta_i\phi_j h(\theta_i, \phi_j)$$

where c_θ and c_ϕ represent the costs of screening for θ and ϕ, respectively. Costs are assumed to be such that it always pays to screen for one and only one characteristic. It immediately follows from (7) that there may be two equilibria, one in which θ is to be used as the "screen," the other in which ϕ is used. When ϕ is being used as a screening device, it does not pay to use θ, and when θ is used, it does not pay to use ϕ. Clearly national income is higher if the former is used rather than the latter. Indeed, it is even possible to construct examples[8] in which everyone is worse off in the former equilibrium rather than the latter! *An attempt to eliminate educational screening may just shift the focus of screening, and make everyone worse off.*

F. *Accurate Screening and Fines*

Another important implication of the possibility of on-the-job screening at any finite cost is that if it is perfectly accurate and individuals are perfectly informed, *the market equilibrium will be characterized by full screening without spending any resources on screening.* The individual agrees to pay the firm a large fine if it turns out he has overstated his ability. The firm announces it will undertake screening of individuals on an assembly line if the output of that assembly line differs from what it should be, given the ability levels which the individuals have declared. Clearly, for a sufficiently high fine, only individuals of ability level θ_1 will declare themselves to be of ability θ_1, and hence no screening need actually be undertaken.

This type of screening often occurs, although in a slightly modified form. Individuals accept low wages while they prove themselves; the low wages today are compensated for by high wages later if they do prove themselves. If they do not, the difference between the low wages and what they could have obtained elsewhere acts as a fine (see Section IIB below and Salop and Salop). Lack of knowledge about one's own abilities and imperfectly accurate screening, combined with risk aversion, places a limit on the efficacy of this kind of screening; if screening is to occur, there will have to be some expenditures for examination. (See the author (1974c).)

---

[8] Let $\theta_1=\phi_1=2$, $\theta_2=\phi_2=1$; $h(\theta_1, \phi_1)=h(\theta_2, \phi_1)=1/3$, $h(\theta_1, \phi_2)=h(\theta_2, \phi_2)=1/6$. Let Y_{ij} be gross income of someone with characteristics (θ_i, ϕ_j). Then with screening for θ: $Y_{11}=Y_{12}=10/3$, $Y_{21}=Y_{22}=5/3$; with screening for ϕ: $Y_{11}=Y_{21}=3$, $Y_{12}=Y_{22}=3/2$. If $C_\theta-1/3\leq C_\phi$, $C_\theta\leq 11/6$, and $C_\phi\geq 4/3$, all individuals are better off under θ screening than under ϕ screening. For these to be equilibria, we require in addition, $1\leq C_\theta\leq 5/3$, and $C_\phi<3/2$. With the further restriction that $C_\theta+C_\phi>9/4$, it can be shown that there are no other equilibria.

G. *Nonexistence of Equilibrium*

We have exhibited examples of too much screening, too little screening, the wrong kind of screening, and multiple equilibria. But another striking aspect of screening models is that ***there may be no competitive equilibrium*** where individuals take the action of others as well as the wages paid to an individual of any label as given.

The simplest example involves a slight modification of the one given in Section IE. For simplicity we present only a numerical version: Let $p(\theta_1, \phi_1)=4$, $p(\theta_2, \phi_2)=2$, $p(\theta_2, \phi_1)=p(\theta_1, \phi_2)=0$, $h(\theta_i, \phi_j)=\frac{1}{4}$, all i, j; let $c_\phi=c_\theta=1.5$. Clearly, there exists no no-screening equilibrium $(4-1.5>1.5)$.

Let us consider alternative possible screenings. Assume $(\theta_1\phi_1)$ screens for θ only. It then pays a fraction (approximately .7) of $(\theta_1\phi_2)$ to screen for θ_1. But this cannot be an equilibrium, for the average wage (after paying for screening) of those screened for θ_1 is then .9; clearly, it pays $(\theta_1\phi_1)$ to screen for ϕ as well. (His net income would then be 1.) But if $(\theta_1\phi_1)$ screens for both θ and ϕ, it does not pay $(\theta_1\phi_2)$ to screen for θ. But if $(\theta_1\phi_2)$ does not screen, it does not pay $(\theta_1\phi_1)$ to screen for both θ and ϕ. Other possibilities (for example, $(\theta_1\phi_1)$ screening for ϕ, partial screening, etc.) may be checked, to see that there in fact exists no equilibrium. (This is similar to the result of Rothschild and the author (1973a).)

II. Screening and Education

Section I established some general characteristics of screening equilibria. We now focus in more detail on screening in educational institutions. Educational institutions are not the only institutions which do screening in our economy. Employment agencies and the College Entrance Examination Board both screen; there is considerable on-the-job screening; how an individual dresses, his accent, his socioeconomic background, his race or ethnic group may all provide bases for screening. The fact that there are other bases for screening does not detract from the importance of educational screening; indeed the screening done by educational institutions provides the primary determinant of one's initial job opportunities and hence of what screening can occur subseqeuntly. In this section we enquire into why educational institutions are important for screening (Section IIA), the mechanisms used for screening (Section IIB), and the implications this has for the structure of the educational system (Sections IIC–E).

A. *Why Educational Institutions?*

Educational institutions provide information about individuals' abilities for a number of reasons: (a) The efficient allocation of scarce educational resources requires the identification of different individuals' abilities, i.e., some individuals would gain little from a Ph.D. program in economics, but would clearly benefit greatly from a course in automobile mechanics, and conversely for other individuals. (b) Most educators would argue that even within a given educational level there are returns from recognizing that some individuals learn certain skills faster than others. (c) Part of the social marginal product of educational institutions is finding each individual's comparative advantage (as educators are wont to say, "helping the individual find out about himself") and information about absolute advantages is almost an inevitable byproduct of obtaining information about comparative advantages. (d) In the interchange between teacher and student which is common to many (but not all) educational processes, the teacher obtains a great deal of information about his student. The fact that there are a large number of teachers making those "observations," makes the information more valuable than the judgment of a single individual (for example, an employer).

In short, it is hard to imagine an educational system which did not obtain some information about individuals. Not all educational *processes* involve screening; that is, large lectures may impart a great deal of information, but the teacher need never ascertain how much of the information the student has absorbed. Some students have even argued that screening diverts them from "real" education to the acquisition of the particular skills and pieces of information which will be tested. Our analysis is predicated on the fact that for the reasons mentioned above, all educational *systems* do some screening.

B. *The Provision of Screening Information: The Screening Mechanisms*

As discussions of grading systems make clear, there is, however, an important difference between obtaining information and making it public. There are several mechanisms by which such information about the individual's capabilities become public:

1) If the education system does any sorting for its own purposes (as it must), the groups into which an individual has been sorted will convey some information to the firm about the individual.

2) Another mechanism is performance tests: individuals have been confronted with roughly similar learning experiences (say geometry). Some individuals "learn" geometry better than others: this fact may be ascertained by a "grade" from the teacher, or by "standardized" objective examination. Failure to pass a course in college, or failure to pass a grade in elementary and secondary schools, conveys a great deal of information, which adversely affects the wages received by those individuals. As long as the school system does any grading, if only on a pass-fail basis, it is providing some information; and even when it does not do the grading itself, others can do the grading for it (Graduate Record Examination, etc.).

3) A great deal of information is provided, however, by *self-selection:*[4] a self-selection mechanism works as follows. Consider any characteristic of an individual about which the individual has more information than the firm. (We do not require that the individual have perfect information, only that on average he be better informed than the firm.) Some individuals have "more" of the given characteristic than others, for example, more brains, more mechanical ability, a higher turnover rate. We construct two (or more) reward-penalty structures such that on average individuals with more of the given characteristics will do better under one reward-penalty structure than under the other, and conversely. If individuals are asked to choose among these reward-penalty structures, and if they are rational, they will sort *themselves* out into those who have more of the characteristic and those who have less. (The better the information of the individuals and the greater the differential rewards, the better the sorting will be.)

Assume that wages are a function of the number of grades completed, and the length of time to complete a grade is a function of the individual's ability. Then if the two functions have the appropriate shape, individuals with lesser ability will quit at a lower grade level than persons with a higher ability. Grade completed is a complete surrogate for ability (see Spence).

---

[4] This is related to Akerlof's theory of lemons (1970). Akerlof argues that the used car market is a self-selection mechanism in which the worst cars become traded. Self-selection mechanisms provide what Spence has called "signals" to the market.

Alternatively, assume we have a hierarchy of schools, from those for the most able to those for the least able. Assume that the schools only use a pass-fail system. Assume that the schools for the more able are more expensive. If individuals had perfect information about their capabilities (and ignoring motivation, emotional, and other problems) in fact no one need ever fail. Students would apply to the school of the appropriate ability.

It should be noted that all these self-selection devices are based on *performance tests;* that is, although the employer is using information from self-selection, self-selection only works because of the performance tests. If there were no *possibility* of failures, everyone would attempt to go to the best school (and then screening would have to be done by admissions committees) and everyone would pass on from grade to grade at the same rate.[5]

C. *The Structuring of Educational Systems*

Although we have argued that an educational system inevitably provides some information about the capabilities of individuals, there are a number of characteristics of the school system which determine how much and what kind of information is provided either by performance test or by self-selection. The school system can decide on the fineness or coarseness of screening. The structure of payments for education and the differences in "levels of education" provided by different schools are also important determinants of the effectiveness of self-screening.

Earlier, we noted that the reason that the school system is the major screening institution in our society is that this information is a natural by-product of its principal activity of providing knowledge (skills) and guiding individuals into the right occupations. In most of the ensuing analysis, we shall employ a stronger hypothesis: the more educational institutions perform their principal functions, the more screening that is produced as a by-product.[6] The more accurately it is able to place individuals into the right "slots," i.e., ascertain their comparative abilities, the more accurately it must ascertain the individuals' absolute abilities. The more knowledge it attempts to impart, the more it is able to "separate the men from the boys." At the extreme, if it tried to teach nothing, there would be no basis for performance testing, and there would similarly be no basis on which the self-screening mechanisms could be based.

There is thus the possibility that in imparting more skills to the abler students, we will simultaneously increase the inequality of income. This has made the organization of the educational system, and the method by which the levels of screening and skill acquisition are determined, an intensely political question.

Many of the social issues involving education arise because of differences in the wealth of parents. It is important, however, to observe that this parental distributional question can at least partly be separated from the questions of educational organization on which we are focusing. Thus the government could provide its support for education in the form of vouchers, allowing individuals to use these in private schools. Even if there were no inequality in parental ability to pay for education, there would be, as we have argued above, important distributional consequences to alternative methods of organizing the educational system. To isolate our attention on these, we shall assume in the subsequent discussion that an individual's attitude towards education is determined completely by the own private monetary returns.[7]

---

[5] This is, of course, not true of other self-selection mechanisms, e.g., those discussed by Salop and Salop. The absence of performance tests plays a crucial role in the economics of self-selection devices discussed by Akerlof (1973), and Rothschild and the author (1973b).

[6] That is, for most of the analysis we shall assume that they are joint products, and that the mix between screening and "skill formation" is technologically determined. We could generalize the model to allow for the determination of this mix. In this paper we will not enquire in detail how the skill acquisition and screening take place (e.g. the nature of the grading system). We shall employ a general formulation which is consistent with a number of alternative microstructures.

D. *The Comprehensive School Systems with Majority Voting and Fairly Accurate Screening*

In this section, we shall show that *with majority voting a comprehensive school system will under reasonable assumptions allocate too many or too few resources to education (screening), relative to the amount which would maximize net national output depending on whether individuals are informed or uninformed about their abilities.*

The model is a slight extension of that presented in Section 1. Individuals are described by a single characteristic θ; the distribution of θ over the population is given by $h(\theta)$. We let λ denote the "intensity" of education.[8] More intensive education (a) costs more, (b) screens better, and (c) increases the productivity of the group educated, either because of skill acquisition or better matching of individuals and jobs.

The Productivity Effect. Let $p(\theta, \lambda)$ be the productivity of an individual of ability θ who has received an education of intensity λ. For simplicity, we shall let p take on the special form (upon appropriate choice of units)[9]

$$(8) \qquad p(\theta, \lambda) = m(\lambda)\theta, \quad m' \geq 0, \quad m'' \leq 0$$

Screening. The educational system places labels on individuals; it gives a point estimate of the individual's ability. Let $e(\theta, \hat{\theta}, \lambda)$ be the probability that an individual of type θ be labelled $\hat{\theta}$, in an educational system of intensity λ. As λ increases, the probability of error decreases, i.e.,

$$(9) \qquad \left.\frac{\partial e(\theta, \hat{\theta}, \lambda)}{\partial \lambda}\right|_{\hat{\theta}=\theta} \geq 0$$

Costs of Education. Finally, we assume that the cost of education per pupil $c(\lambda)$ is an increasing function of λ and that the marginal cost also increases with λ.

$$(10) \qquad c' > 0 \quad \text{and} \quad c'' > 0$$

In a comprehensive educational system all schools have the same value of λ. The model includes as special cases the traditional model of pure skill acquisition ($\partial e/\partial\lambda = 0$) and the pure screening model ($m' = 0$).

Wage Determination. Workers whose ability is estimated to be $\hat{\theta}$ receive a wage equal to their mean marginal product

$$(11) \qquad w(\hat{\theta}) = m(\lambda) \int \theta e(\theta, \hat{\theta}, \lambda) h(\theta) d\theta \div \int e(\theta, \hat{\theta}, \lambda) h(\theta) d\theta$$

---

[7] This would be the case for instance even without government redistribution if (a) there were a perfect capital market, (b) education were not a consumption good, and (c) there were no tax distortions in the allocation of capital between human and physical capital.

[8] Throughout the discussion we make the extreme assumption that all information about individuals' abilities is obtained through the educational system, and hence the individuals' wages are determined by the label imposed by the schools. Obviously, there is some information obtained on the job. The qualitative results of our analysis will, however, be unaffected so long as (a) firms cannot obtain information on the job instantaneously, and/or (b) there are any fixed costs of hiring and training. Intensity can be thought of as either "length" (number of years of schooling) or "quality" within a program of fixed length.

[9] It should be noted that the model may be considerably generalized without affecting its qualitative properties. In particular, the restriction embodied in equation (8) may be dropped, and an additional kind of education which increases skills without screening may be introduced. See the author (1972b).

The expected wage which a person whose true ability is θ will receive is then given by

$$W(\theta) = \int w(\hat{\theta})e(\theta, \hat{\theta}, \lambda)d\hat{\theta} \tag{12}$$

We shall consider the special case of a fairly accurate grading system in which $e(\theta, \hat{\theta}, \lambda)$ takes on the form

$$e(\theta, \hat{\theta}, \lambda) = f(\theta - \hat{\theta}, \lambda) = f(\epsilon, \lambda) \tag{13}$$

where $\epsilon = \theta - \hat{\theta}$ is the error. We thus assume that the distribution of error is independent of the value of θ. Moreover, we assume $E\epsilon = 0$ and $E\epsilon^2 = g(\lambda)$, $g'(\lambda) \leq 0$. Thus from (11)

$$w(\hat{\theta}) = m(\lambda)\hat{\theta} + \frac{m(\lambda)\int \epsilon f(\epsilon, \lambda)h(\hat{\theta} + \epsilon)d\epsilon}{\int f(\epsilon, \lambda)h(\hat{\theta} + \epsilon)d\epsilon} \tag{14}$$

$$\simeq m(\lambda)\left[\frac{h'(\hat{\theta})g}{h(\hat{\theta})} + \hat{\theta}\right]$$

(15)

$$W(\theta) \simeq m(\lambda)\int\left[\hat{\theta} + \frac{h'(\hat{\theta})}{h(\hat{\theta})}g\right]f(\theta - \hat{\theta}, \lambda)d\hat{\theta}$$

$$= \int\left[m(\lambda)(\theta - \epsilon) + m(\lambda)\frac{h'(\theta - \epsilon)}{h(\theta - \epsilon)}g\right]f(\epsilon, \lambda)d\epsilon$$

$$\simeq m(\lambda\left[\theta + \frac{h'(\theta)}{h}g\right] \gtrless m(\lambda)\theta \text{ as } h' \gtrless 0$$

Thus in an unimodal distribution, individuals below the mode get more than they would under perfect screening, individuals above the mode get less than they would. The reason for this is that individuals are being averaged with some individuals who are better than they are, but have been underrated, and some who are worse, but who are overrated; if there are more who are worse (within a given range of error) than who are better, the individual will receive less than his true marginal productivity (on average).

Output Maximizing Educational Intensity. If we wish to maximize national output less educational expenditures, i.e.,

$$\max\left\{m(\lambda)\int \theta h(\theta)d\theta - c(\lambda)\right\} \tag{16}$$

we set

$$c'(\lambda) = \bar{\theta}m'(\lambda) \tag{17}$$

where $\bar{\theta}$ is the mean level of ability in the economy. The solution to (17) we shall call the "optimal level of education," bearing in mind that we are using the term in a very restricted sense.

Majority Voting. We now come to the choice of an educational intensity (and the associated degree of screening) in a majority voting political system. We assume the educational system is paid for by proportional wage taxes. Then if τ is the tax rate,

$$\tau m(\lambda)\bar{\theta} = c(\lambda) \tag{18}$$

and the net expected wage of someone at ability θ (using (15) and (18)) is

$$W(\theta)(1 - \tau) \tag{19}$$

$$\simeq m(\lambda)\left[\theta + \frac{h'}{h}g\right]\left(1 - \frac{c(\lambda)}{m(\lambda)\bar{\theta}}\right)$$

$$= \left(\theta + \frac{h'}{h}g\right)\left(m(\lambda) - \frac{c(\lambda)}{\bar{\theta}}\right)$$

Taking the derivative of (19), we can see how varying educational intensity affects different groups

$$\frac{dW(1 - \tau)}{d\lambda} = \frac{W}{m}\left(m' - \frac{c'}{\bar{\theta}}\right) + (1 - \tau)m\frac{h'}{h}g'$$

This depends on both θ and λ. Consider the optimal level of education. Note then that the first term drops out, and we are left with only the second term: individuals above the mode will want more than the optimal level of education, individuals

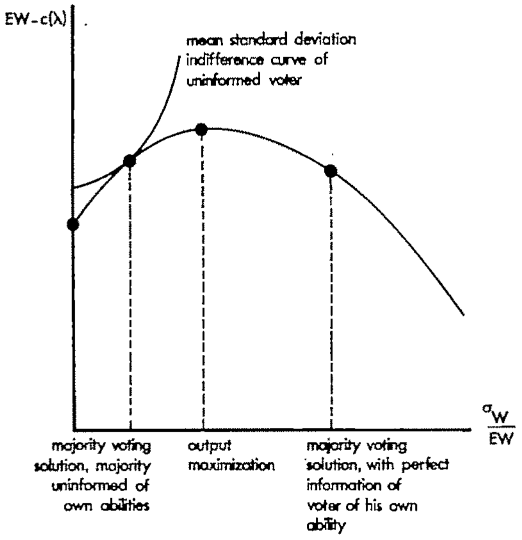

FIGURE 1

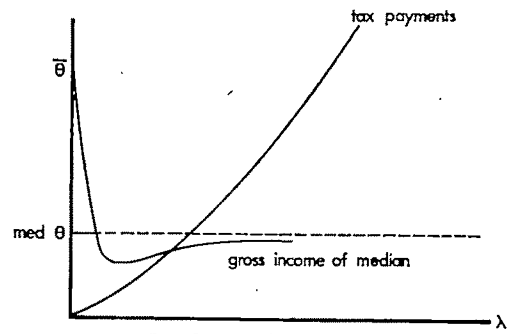
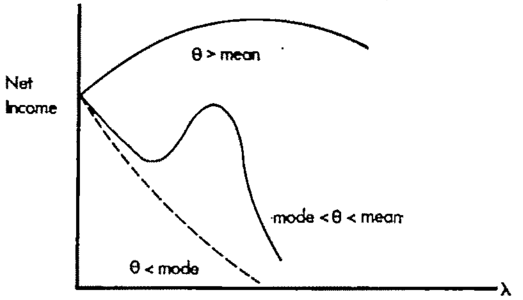


Pure Screening (no productivity effects)



Screening (with productivity effects)

FIGURE 2

below the mode will want less. It is possible to show that if c'', $g''\geq 0$, and $m''<0$, preferences will be single peaked. Thus, the majority decision will be determined on the basis of the median value of h'/h. It is clear that if the mode lies below the median as it does for the income distribution, there will be an excess of investment in education over the optimum amount.

Indeed, it is easy to establish that not only is output lower, but the coefficient of variation in after tax expected wage income is greater, as illustrated in Figure 1.

It is worth noting at this point a major difference between fairly accurate screening systems and those which, for low values of λ, are very inaccurate. Take as an extreme case a system in which with "no information" and no education everyone receives the average value of the marginal product, as discussed earlier. Assume education only screens and that the distribution of abilities is lognormal. With no screening, the median receives the average, with perfect screening, he receives the median. As screening increases, his gross income initially declines. The cost of education increases with screening. Thus, there are two "peaks" to his net income, and accordingly there may not exist a majority voting equilibrium.[10] (See Figure 2.)

The above analysis assumed that everyone knew perfectly his own ability. The other polar case is where at least a majority of individuals are completely uninformed as to their abilities, i.e., their subjective probability distribution of their abilities is identical to the frequency distribution of abilities in the population. It is clear then that the median voter will vote for a level of education which is below that which maximizes net national output.

E. *Noncomprehensive School Systems*[11]

Although there is an institutional and analytical simplicity to a comprehensive school system, it is easy to establish that in general net national output is not as high as in a system in which different individuals receive a different education. Indeed, if by greater ability we mean in part the ability to learn more easily, then it is more efficient (if our objective is maximizing net national output) to spend more resources on the more able.[12] This will be a characteristic of most noncomprehensive school systems. The allocation, however, will differ between a governmentally organized system attempting to maximize net national output, a private educational system, and a mixed public-private system. A full analysis would take us beyond the scope of this paper, but what we wish to do here is to characterize the major reasons that the equilibrium in pure private as well as mixed public-private systems does not maximize net national income.

---

[10] I am indebted to John Chant for discussions on these points.

[11] For a more extensive discussion of the issues discussed here as well as the development of a formal model, the reader is referred to the author (1972b, 1974).

For simplicity, it is best to return to the special case of Section IA, where there are only two ability groups in the population. The school system will consist of two schools, one run for the more able, one for the less able. In the mixed public-private school system, the school for the more able is private, for the less able, public. Private schools charge a tuition equal to per pupil expenditure; public schools raise revenue by general proportional taxation. We assume that the less able are in the majority. Each school system will have some of both kinds of individuals, the upper school will contain some individuals of lower ability who are attempting the "gamble" of being able to pass through the system and hence be grouped with the more able, and those of lower ability who overestimate their ability. Conversely for the lower school.

We shall now argue that there is some presumption for excessive expenditure even in a private school system. Consider the three effects of an increase in educational expenditure in the upper school. First, there is the direct productivity effect. Since the upper school focuses its attention on those who will "succeed," it spends more on this account than a government-run school which is also concerned with those who do not succeed in the upper school. Secondly, there is the direct screening effect, which, as we argued above, is simply redistributive in character, and again leads to "too much" spending on education. Thirdly, there is the "self-selection effect." By increasing educational expenditure and the quality of screening, the upper school discourages those of lower ability from attempting to go to the upper school. There is some social return to this, since the amount of education which is optimal for the less able is less than that which is optimal for the more able. The private return, however, is derived not from the increased "efficiency" of the educational system, but from the ability of the more able to capture more of their "ability rents." The private return to self-selection may be more or less than the social return. Thus, only if the social return to self-selection exceeds the private return by just the right amount to compensate for the excess of the private productivity and direct screening returns over the social returns will the level of expenditure be at the output maximizing level; normally we would expect there to be too much expenditure in the upper school.

A similar analysis applies to the lower school. It is obviously not in interests of those of lower ability to have extensive screening. Although the social return to self-selection is positive, the private return to those of lower ability is negative. By increasing the level of educational expenditures they are, however, able to attract those of higher ability who are less sure of their abilities and more risk averse.

---

[12] Although the precise quantitative relationship clearly depends on the specific technological assumption embedded in equation (8) so long as some are able to learn more quickly and easily than others, the result remains valid.

This again leads to some presumption of excess spending even in the lower school. When the lower school is publicly financed, there is a further incentive for excess spending, since now the costs for the lower school are borne by the population as a whole.

F. *Concluding Comments*

In recent years economists have shown an increasing awareness of "market failures" and have increasingly called upon government intervention to correct these failures. But to turn over an allocation process to the public sector is to make it subject to "political laws" which may be no less forceful—and even less efficient—than the "economic laws" which previously governed the allocation process. The fact that these political laws are less well understood, perhaps more amorphous, than the corresponding economic laws is not an excuse for relying on the mythical "benevolent despot" who plays the central role in most economists' models of the public sector.

The educational sector provides an important point of comparison between the two allocation processes. If, as we have suggested, education provides information as well as skills, then it is providing a "commodity" for which it is well known that the market "fails"; we have shown how social returns differ from private returns and have examined in detail the market allocation of resources to education as well as the structure of the educational system which would emerge from a simplified political process in a highly idealized setting. Some important results emerge. Screening has productivity returns, but tends to increase inequality. There will thus be a tradeoff between efficiency and distributional considerations; but beyond a certain point, further increases in educational expenditure may both increase inequality and decrease net national income. We noted a tendency for all the school systems examined—public, private, and mixed—to operate at these levels even when all citizens are simply concerned with their own income maximization. One of the reasons for this—found in all of the systems—is that some of the returns to higher levels of education (those returns derived from the increased accuracy of labelling individuals' abilities), are private but not social returns; we argued that if abilities are distributed skewly to the right, for the median voter these private returns were positive. A further reason, in publicly supported systems, is that the median voter pays for less than his proportionate share in marginal costs. As a result, the tendency for excessive spending on education may be greater in the publicly financed schools.

On the other hand, it should be emphasized, that whether there is "too much" or "too little" screening in a competitive economy depends on a number of assumptions concerning the screening technology, how well-informed individuals are concerning their own abilities, the nature of the production process, and whether screening is primarily hierarchical or "job-matching."

Finally, we note that attempts to curtail educational screening may simply shift the focus of screening (for example, to on-the-job screening), with the possibility of a lowering of net national output without any commensurate gain in equality.

Substitution Effects and Biases in Nontrue Price Indices

By P. J. LLOYD*

A number of indices of prices such as the Laspeyres and Paasche are commonly used to compare price movements between two or more situations, but they are not true price indices. When the commodities purchased are final consumer goods, the true price index, or the true "cost of living" index as it is often called, is defined by Paul Samuelson and S. Swamy as ". . . the ratio of the (minimum) costs of a given level of living in two price situations" (p. 567). One may define a true cost of production index for a single commodity or a fixed bundle of commodities, or for national production possibilities (see the survey by Samuelson and Swamy), in an analogous way. Unfortunately, the quantities of commodities that would be purchased in at least one situation are not directly observable.

Two approaches to the measurement of true indices have been developed. The first is to establish upper and lower limits, preferably in terms of price indices using observable data, within which the true measure must lie; Ragnar Frisch and Samuelson (1947, pp. 156–63) survey several known limits. The second is to make direct estimates of true price indices. These have been made, so far as I am aware, only for the rather special case of consumer price movements on the maintained hypothesis that the consumer's utility function[1] is Stone-Geary (see Arthur Goldberger and Theodore Gamaletsos, and Tran Van Hoa). I shall extend this second approach.

Section I presents the true price index in terms of the minimum expenditure function. In addition to yielding, by definition, direct estimates of the true price index, this function also provides a relatively simple way of exploring its properties.

Two special properties of these indices are considered under the assumptions that the utility functions are homothetic or homogeneously separable. As an illustration, true cost of living indices are derived for a number of particular utility (production) functions. In Section II one of these functions, the two-level *CES* function of Kazuo Sato, is used to find the magnitude of the bias in the estimates of true price indices obtained by employing Laspeyres or Paasche indices. Contrary to the indications of the restrictive Stone-Geary function, the bias can be substantial for realistic parameter values and price movements. In Section III, I indicate how the methods used may be extended to incorporate leisure, multiperiod consumption and saving, and durable goods in the model. The paper will not cover other problems of index construction, such as those posed by changes in tastes (see

---

* Australian National University. I am indebted to Ted Sieper, Sundrum, Stephen Turnovsky, and a referee for comments on an earlier draft. Section I has been revised and condensed, taking advantage of the survey by Paul Samuelson and S. Swamy published earlier in this *Review*.

[1] A third approach is to derive an approximation to the price index by assuming some linear, quadratic, or higher-order approximation to the iso-utility surface (see Frisch, pp. 27–31, for several earlier examples) or to the ordinary commodity demand functions (see Lawrence Klein and Herman Rubin) or to total expenditures (see Henri Theil). See also Samuelson and Swamy.

Samuelson and Swamy), or qualities of commodities (see Franklin Fisher and Karl Shell), the presence of public goods, and the need to aggregate across individual buyers.

I

We are concerned with obtaining for a single consumer the true price index from a utility function which is assumed to represent in an order-preserving way his binary preference orderings and which does not vary over situations. There are n commodities. All results carry over to the analogous problems in production theory.

The consumer acts to maximize his utility function

$$U = U(q_1, \dots, q_n) \tag{1}$$

subject to the budget constraint

$$\sum_i p_i q_i = m, \qquad m = \text{constant}$$

The true price index measuring the change in the level of prices between two situations, situation 0 and situation 1, is defined as

$$T = e^1/e^0 \tag{2}$$

where

$$e = \min \left\{ \sum_i p_i q_i \,\middle|\, U(q_1, \dots, q_n) = \mu \right\}$$

for a given set of prices. It is immediately apparent that the true price index is simply the ratio of two values of the minimum expenditure or support function[2] (see Ronald Shephard (1953, ch. 3) or Lionel McKenzie). The function e is linearly homogeneous in its price arguments. From the definition of e

$$T = \overset{1}{e}(\overset{1}{p}_1, \dots, \overset{1}{p}_n; U)/\overset{0}{e}(\overset{0}{p}_1, \dots, \overset{0}{p}_n; U) \tag{3}$$

That is, the true price index is in general a function of prices in situations 0 and 1 and of the chosen level of utility. It is customary but not necessary to take the level of utility in situation 0 as the level of utility to which the two minimum expenditures relate. In this case

$$T = \sum_i \overset{1}{p}_i \overset{*}{q}_i \Big/ \sum_i \overset{0}{p}_i \overset{0}{q}_i \tag{4}$$

where now the denominator is the actual expenditure in situation 0 under the assumption of utility maximization; that is, $e^0 = m^0$. The numerator is the minimum total expenditure required to attain the level of utility in situation 0, given the set of prices in situation 1. We shall use this case throughout as an illustration. In this case $(q_1^*, \dots, q_n^*)$ for situation 1 cannot be observed from market behavior.

The index may be written as the weighted arithmetic mean of ratios of minimum expenditures for each commodity, or for groups of commodities. From the definition

$$T = \sum_{j=1}^{m} \overset{1}{e}_j \Big/ \sum_{j=1}^{m} \overset{0}{e}_j \qquad m \leq n \tag{5}$$

$$= \sum_{j=1}^{m} (\overset{1}{e}_j/\overset{0}{e}_j) w_j \qquad \sum_j w_j = 1 \tag{6}$$

where $e_j = p_j q_j$ is the cost-minimizing expenditure on commodity or commodities j and $w_j = e_j^0 / \sum_j e_j^0 > 0$ is the share of commodity j in the total expenditure of situation 0. In general the quantity of each commodity and therefore each e_j will depend on the prices of all commodities. These ratios of expenditures are not the price relatives (p_j^1/p_j^0), except in the case of fixed consumption proportions (see equation (26) below). T may also be writ-

---

[2] There is an alternative method of derivation of T from the indirect utility function $U = \psi(p_1, \dots, p_n; e)$ which has been used by Goldberger. For a chosen U,

$$U = \psi(\overset{0}{p}_1, \dots, \overset{0}{p}_n; \overset{0}{e}) = \psi(\overset{1}{p}_1, \dots, \overset{1}{p}_n; \overset{1}{e})$$

we may solve for e^0 and e^1 which are as before, the minimum expenditure to attain U, given prices in the two situations. The duality of the indirect and direct utility functions has also been used for homothetic functions by Samuelson and Swamy.

ten as a general mean of the set of all price relatives $(p_1^1/p_1^0, \ldots, p_n^1/p_n^0)$.

When further restrictions are imposed on U or ψ, the form of the true price index itself may be further restricted. One basic question is: Under what restrictions can we obtain an index in which m^0 does not appear as an argument, that is, in which the true price change is independent of the initial level of utility and expenditure?

THEOREM 1: (*The Bergson-Shephard Theorem*);[3] *The true price index may be written in the form*

$$(7)\quad T = P(\overset{1}{p}_1, \ldots, \overset{1}{p}_n)/P(\overset{0}{p}_1, \ldots, \overset{0}{p}_n)$$

where $P(p_1, \ldots, p_n)$ *is homogeneous of degree one, if and only if the utility function,* U, *is homothetic.* (For proof of this well-known theorem see Shephard (1970) or Samuelson and Swamy.) Homotheticity gives utility functions the special geometric property that all level surfaces can be obtained by radial expansion from the origin of the unit level surface. Given a set of initial prices and hence a cost-minimizing set of commodity proportions, a new set of commodity prices must result in a certain proportionate change in expenditure to maintain the initial level of utility, and therefore, a certain value of T, independent of the initial level of expenditure. This family of utility functions is free of the objection that the true price index is arbitrary because it applies only to a particular level of utility (see R. G. D. Allen, pp. 289–90).

Another interesting question is the conditions under which the true price index may be written as some function of sub-indices for the prices of groups of commodities, and therefore, the movement of prices between two or more periods may be decomposed into the movements due to the prices of the separate groups of commodities. This is not, in general, possible but a condition that is sufficient (but not necessary)[4] may be derived readily from a well-known aggregation theorem.

THEOREM 2: *The true price index may be written in the form*

$$(8)\quad T = e(\overset{1}{\bar{p}}_1, \ldots, \overset{1}{\bar{p}}_m; \overset{0}{U}) / e(\overset{0}{\bar{p}}_1, \ldots, \overset{0}{\bar{p}}_m; \overset{0}{U})$$

where $\bar{p}_j = \bar{p}_j(p_1^j, \ldots, p_{n_j}^j)$, $j = 1, \ldots, m < n$; $\sum_{j=1}^m n_j = n$ *if the direct (or indirect)*[5] *utility function is homogeneously separable.* Note that $\bar{p}_j$ is the price for the jth group of commodities $(q_1^j, \ldots, q_{n_j}^j)$. A utility function is said to be homogeneously separable with respect to a partition of the n primary commodities into m mutually exclusive and exhaustive subsets if and only if:

$$(9)\quad U = V(\overset{1}{v}(\overset{1}{q}_1, \ldots, \overset{1}{q}_{n_1}), \ldots, \overset{j}{v}(\overset{j}{q}_1, \ldots, \overset{j}{q}_{n_j}), \ldots, \overset{m}{v}(\overset{m}{q}_1, \ldots, \overset{m}{q}_{n_m}))$$

$$j = 1, \ldots, m < n; \qquad \sum_{j=1}^{m} n_j = n$$

---

[3] Earlier, Frisch (p. 17) proved that homotheticity under the different name of "expenditure proportionality" is a sufficient condition for equation (7). Commenting on Frisch, Abram Bergson proved the necessity of this restriction, pp. 42–45, 49–50. Shephard proved the theorem again (1953, pp. 43–48 and 1970, p. 304). Homotheticity has long been known in the theory of price indices for another effect. Frisch showed that if the condition of expenditure proportionality holds, the true price index lies between an upper bound determined by the Laspeyres Index and a lower bound determined by the Paasche Index.

[4] The Hicks condition of fixed relative prices for the grouped commodities provides an alternative sufficient condition.

[5] If T is derived from the indirect utility function, homogeneous separability of ψ is a sufficient condition. The indirect utility function is homogeneously separable if and only if the direct utility function is homogeneously separable. (Similarly U is homothetic if and only if ψ is.) This is an application of the duality properties of direct and indirect utility functions (see Samuelson (1965)).

where V is continuous, twice differentiable, and strictly quasi concave and the v_i are continuous, twice differentiable functions, homogeneous of degree one.

W. M. Gorman has shown that if the utility function is homogeneously separable, commodities may be consistently aggregated in the sense that one may form composite commodities from the homogeneously separable groups which may be treated in the same manner as the primary commodities. In particular, the commodity demand functions of composite commodities so formed have all the usual properties (see, for example, Donald Katzner, pp. 140–43). One immediate implication is that the expenditure function, and hence the true price index, is separable in the same grouping of commodities.[6] Moreover, it can be shown that the price functions for the composite commodities are themselves homogeneous of degree one in the prices of the component commodities (see Shephard (1970, ch. 6)). We may therefore form ratios of the prices $(\bar{p}_j^1/\bar{p}_j^0)$ which are price sub-indices satisfying, like T, all the Fisher test criteria (see Samuelson and Swamy for discussion of these tests). T may also be written as a mean of the ratios of the prices $(\bar{p}_j^1/\bar{p}_j^0)$.

A few particular functions will illustrate these principles. First, consider the Stone-Geary utility function which has been used to estimate true indices:

$$U = \sum_{i=1}^{n} \beta_i \, log\,(q_i - \gamma_i)$$

$$0 < \beta_i < 1, \quad \sum_i \beta_i = 1, \quad q_i > \gamma_i \geq 0$$

The associated true price index may be derived by integration of the derived commodity demand functions (see Klein and Rubin, and Samuelson (1947)), or from the indirect utility function (see Goldberger), or from the expenditure function. The function e may be found to be

$$(10) \quad e = \sum_{i=1}^{n} p_i\gamma_i + c\prod_{i=1}^{n} p_i^{\beta_i}$$

$$c = c(U) = \text{constant for } U = \mu$$

In its most convenient form T may be written as

$$(11) \quad T = s^{0}\sum_{i=1}^{n} w_i^{0}(p_i^{1}/p_i^{0}) + t^{0}\prod_{i=1}^{n} (p_i^{1}/p_i^{0})^{\beta_i}$$

Thus the true index is the weighted arithmetic mean of two sub-indices as required by equation (6). The first is the sub-index of the cost of buying the subsistence quantities of the commodities $(\gamma_1, \ldots, \gamma_n)$, and the second is the sub-index of the cost of buying the above-subsistence quantities of the same commodities. These two sub-indices are themselves weighted arithmetic and geometric means of price relatives, the weights being the corresponding shares of subsistence and above-subsistence expenditure, respectively.

It may be noted that the Stone-Geary utility function is homothetic in the variables $(q_1-\gamma_1, \ldots, q_n-\gamma_n)$, that is, the above-subsistence quantities consumed of the commodities. Alternatively, the Stone-Geary function may be said to be homothetic to the point $(\gamma_1, \ldots, \gamma_n)$. This is a generalization of the definition of homotheticity to the origin. Equation (11) exemplifies that the true price index for a function which is homothetic to some point other than the origin is not independent of the initial level of income.

An example of a homothetic function is the n-commodity (Bergson) or generalized *CES* function (see Hirofumi Uzawa):

$$(12) \quad U = \left[\sum_{i=1}^{n} \alpha_i q_i^{-\rho}\right]^{-1/\rho} \qquad \alpha_i > 0, \rho > -1$$

---

[6] Shephard (1953) proved that homogeneous separability was sufficient for aggregation of the separable variables in the cost function of a producer but did not apply the result to the theory of price indices.

This function has the special property that the partial elasticity of substitution (σ) between any pair of commodities is constant and identical for all pairs. The expenditure function is (see Uzawa, p. 293):

$$(13)\quad e = U\Big[\sum \overset{\sigma}{\alpha}_i p_i^{1-\sigma}\Big]^{1/1-\sigma} \qquad \sigma = 1/(1+\rho)$$

It is easily shown that T can be written in the useful form

$$(14)\quad T = \left[\sum_{i=1}^{n} \overset{0}{a}_i(\overset{1}{p}_i/\overset{0}{p}_i)^{1-\sigma}\right]^{1/1-\sigma}$$

where

$$a_i = p_i q_i/e$$

$$= \overset{\sigma}{\alpha}_i(p_i/p_n)^{1-\sigma}\left[\sum_j \overset{\sigma}{\alpha}_j(p_j/p_n)^{1-\sigma}\right]^{-1}$$

It is seen that a_i, the share of each commodity in total expenditure, depends solely on relative prices. The true price index is independent of the initial level of utility as required by Theorem 1. Moreover, equation (14) shows that the index takes a special form. It is the weighted mean of order $(1-\sigma)$ in the price relative variables, the weights being the initial period budget shares. This mean form follows from the expenditure function being a weighted mean of order $(1-\sigma)$, and its dual the direct utility function a weighted mean of order $-\rho$ (see Kenneth Arrow, et al.). Thus the expenditure function e (and hence the true index T) and U are self-duals in the sense that they have the same functional form.[7]

As special cases with $\sigma = 0$ and 2, we have the weighted arithmetic and harmonic means, respectively. The limiting case of the *CES* function as $\sigma \rightarrow 1$ or that of the Stone-Geary function as $\gamma_i \rightarrow 0$ for all i, is the Cobb-Douglas function

$$(15)\quad U = \prod_{i=1}^{n} q_i^{\beta_i} \qquad \beta_i = \alpha_i \Big/ \sum_{i=1}^{n} \alpha_i$$

Its associated price index is, from equation (11) or (14), (see G. H. Hardy, J. F. Littlewood and G. Polya, p. 15):

$$(16)\quad T = \prod_{i=1}^{n} (\overset{1}{p}_i/\overset{0}{p}_i)^{\beta_i} \qquad \sum_{i}^{n} \beta_i = 1$$

Thus, the geometric mean is derived as an exact true price index under the hypothesis that U is Cobb-Douglas.

The use of homogeneous separability may be exemplified by the two-level generalizations of the *CES* functions which were developed in production theory. The utility function corresponding to the two-level Sato generalization is

$$(17)\quad U = \left[\sum_{j=1}^{m} \alpha_j(\bar{q}_j)^{-\rho}\right]^{-1/\rho} \qquad \alpha_j > 0 \quad \rho > -1$$

where $\bar{q}_j$ is a quantum index function of the form

$$(18)\quad \bar{q}_j = \left[\sum_i \overset{j}{\alpha}_i(\overset{j}{q}_i)^{-\rho_j}\right]^{-1/\rho_j}$$

$$\overset{j}{\alpha}_i > 0, \quad \rho_j > -1$$

Thus U in equation (17) is a *CES* function in variables $\bar{q}_j$ which, as in (18), are themselves *CES* functions of the quantities of commodities actually marketed. The first function of the composite commodities $\bar{q}_j$ in equation (17) will be described as the "top level," and the second function in equation (18) as the "bottom level." The partial elasticities of substitution between any two commodities i and k are given by (see Sato):

> $\sigma_{ik} = \sigma_j$ if i and k are in the same group j, and a harmonic mean of σ, σ_r, and σ_s if i and k are in two distinct groups, r and s.

The implied expenditure function is shown as (19).

---

[7] Self-duality of the direct and indirect utility functions U and ψ, has been considered by Samuelson (1965, p. 793n) and Houthakker.

$$(19) \qquad e = U\left[\sum_{i=1}^{m} \alpha_j^{\sigma} \bar{p}_j^{\,1-\sigma}\right]^{1/1-\sigma}$$

where $\bar{p}_j$, the price of the commodities in the jth group is

$$(20) \qquad \bar{p}_j = \left[\sum_{i=1}^{n} \alpha_i^{\sigma_j} (\overset{j}{p}_i)^{1-\sigma_j}\right]^{1/1-\sigma_j}$$

$$\sigma_j = 1/(1+\rho_j)$$

Hence, by the definition of T and applying equation (14)

$$(21) \qquad T = \left[\sum_{j=1}^{m} \overset{0}{\bar{a}}_j (\overset{1}{\bar{p}}_j/\overset{0}{\bar{p}}_j)^{1-\sigma}\right]^{1/1-\sigma}$$

$$\bar{a}_j = \bar{p}_j \bar{q}_j / e$$

where

$$(22) \quad \overset{1}{\bar{p}}_j/\overset{0}{\bar{p}}_j = \left(\sum_i [(\overset{j}{a}_i)^0][(\overset{j}{p}_i)^1/(\overset{j}{p}_i)^0]^{1-\sigma_j}\right)^{1/1-\sigma_j}$$

$$\overset{j}{a}_i = \overset{j}{p}_i \overset{j}{q}_i / \overset{j}{e}$$

T is a weighted mean of order $(1-\sigma)$ in variables which are themselves weighted means of order $(1-\sigma_j)$.

We see from equation (21) that the true price index for the two-level *CES* function is independent of the initial level of expenditure and is self-dual with the two-level direct utility function and expenditure functions. Finally, the index may be written in terms of the price relatives $(\bar{p}_j^1/\bar{p}_j^0)$. These are price sub-indices for each separable group of commodities. That T may be written in this form is the result of the joint restrictions of homogeneity and homogeneous separability. We shall refer to the index in equation (21) which is a function of the sub-indices as the top-level index and to the sub-index for each commodity group in equation (22) as the bottom-level indices.

II

The most important question is the extent of the bias that arises in empirical studies of price movements, where a non-true price index is employed when a true price index should be employed. In most cases the index employed is a Laspeyres or Paasche index with fixed base or current period weights, respectively. In all cases the extent of the bias will depend on the pattern of relative price and income movements between the situations compared and the changes in consumption in response to these price changes. In the case of fixed period weights the bias arises because these indices ignore the substitution of now relatively cheaper commodities for those whose relative prices have increased, which is a consequence of utility maximization. In the cases of other indices, the bias arises either because the index is a true price index derivable from some utility function which may not be a sufficiently good representation of consumer's preferences, or because the set of weights used is not consistent with any utility maximization process.

In any particular instance the extent of the bias upon discrete changes will of course depend on both the index which has been arbitrarily chosen and on the particular utility function which it is believed truly represents the consumer's preferences. The function selected for this purpose is the Sato two-level *CES* function with two groups of two commodities each, a total of four commodities.

It may be objected that the results below are limited by the use of a particular functional form. This function is restricted in that it is homogeneous of degree one and the intragroup elasticities of substitution for commodities σ_j and of substitution between commodity groups σ are constant. Homogeneity is not a serious additional restriction for production processes but the reality of it, or rather its homothetic transformations, may be questioned for the analysis of consumer behavior. However, in this context homogeneity is an advantage as it removes the income effect. Although the true price index is defined with respect to a chosen level of utility, the arbitrary choice of this level for a time-series may affect substantially the values of the true index and the bias from calculating a nontrue index if the utility function is not homothetic and the income elasticities differ markedly among commodities. Similarly, the constancy of the partial elasticities of substitution between commodities within the same group and between commodity groups allows one to measure the importance of substitution effects directly by varying these substitution parameters. An additional advantage of the function is that the Laspeyres, geometric, and harmonic means are all special cases of the derived price index.

Table 1 presents a range of values for the index T^* for selected representative price changes and parameter values. The index T^* is

$$T^* = 100[a_x r_x^{1-\sigma} + a_y r_y^{1-\sigma}]^{1/(1-\sigma)} \tag{23}$$

where r_x and r_y are the chosen price relatives. The expression has been multiplied by 100 to put it in the form conventional for computation. It can apply to either the top level or the bottom level. To obtain the true price index for the n commodities, one first applies this expression to obtain changes in the commodity prices for each group of commodities at the bottom level given the selected parameter values. One then repeats the calculation at the top level given the computed sub-price indices and the selected values for other top level parameters. In general, the parameter values will differ between the two levels.

The commonly used Laspeyres index will be used to show the bias from misspecification. The divergence between the true index for given price changes and the Laspeyres index with fixed base period weights *at one level* can be seen from Table 1. The use of fixed weights corresponds to the assumption of zero substitution in response to relative price changes. The Laspeyres index is an upper bound of the true index. The values of this index are given by the first row of the table with $\sigma=0$. Since errors occur at both the top and bottom levels if the utility and true price index functions are assumed to be Laspeyres when in reality they are two-level *CES* with $\sigma>0$ and $\sigma_j>0$ for $j=1$ and 2, Table 1 alone does not reveal the total bias from the use of the Laspeyres index.

TABLE 1—T^* FOR REPRESENTATIVE PRICE CHANGES[a]

	$a_x=0.3$			$a_x=0.7$

Table 2 presents the figures of the total percentage bias B which result from using the Laspeyres index in place of the true two-level *CES* index:

$$B = \left(\frac{L - T}{T - 100}\right) 100 \tag{24}$$

where

$$L = \left[\sum_{i=1}^{4} \overset{1}{p}_i \overset{0}{q}_i \Big/ \sum_{i=1}^{4} \overset{0}{p}_i \overset{0}{q}_i \right] 100$$

$$= \sum_{i=1}^{4} \overset{0}{a}_i (\overset{1}{p}_i / \overset{0}{p}_i) 100 \tag{25}$$

$$\overset{0}{a}_i = \overset{0}{p}_i \overset{0}{q}_i \Big/ \sum \overset{0}{p}_i \overset{0}{q}_i$$

and T is given by equation (21) with $j=1$, 2 and $n_j=2$, multiplied by 100. The bias examined is the bias in the *change* in the value of the index in later periods or situations from the value in the base or initial situation of 100. This is reasonable since the purpose of indices is to measure these changes from base values and it is this bias which is important in applications of index numbers. The bias has been computed by first computing the true index and the corresponding Laspeyres index and then using equation (24). The true index is computed in two stages. The first stage is the calculation of the T^* for each group of commodities from equation (23). For the second stage we take as a representative sample of the true price changes for the two groups of commodities certain pairs of the values in Table 1 which have been marked by a square. The parameter values at the bottom level which give rise to these sub-price indices are given at the columns and rows of this table. We then use T^* at the top level, using these sub-price indices. The top level substitution and distribution parameters are given at the columns and rows of Table 2.

One would expect the biases from neglecting substitution to increase with the elasticities of substitution. The purpose of this approach has been to indicate how other aspects of price movements and these elasticities affect the magnitude of these biases. The qualitative properties of the bias function in equation (24) emerge from Tables 1 and 2. The bias is an increasing function of the elasticities of intergroup substitution σ, the elasticities of intragroup substitution σ_j, the change in the relative prices of individual commodities (which is reflected in difference in the price relatives), the budget share at the bottom level of the commodity whose price index has changed least, and the budget share at the top level of the group of commodities whose price index is most overstated by use of the Laspeyres subindex. The effect on the bias of increasing the elasticities of substitution at either level can be verified from the theorem of means: a mean of order s is less than the corresponding mean of order t unless the components (here the price relatives) are all equal or $t \leq 0$ and one component is zero (see Hardy, Littlewood, and Polya, p. 26). In our expression s, $t=(1-\sigma)$. The influence of other parameters can be appreciated if we write the Laspeyres index in terms of the primary commodities as an arithmetic mean of sub-indices for commodity groups which are themselves arithmetic means. For the general case of n commodities,

$$L=\left[\sum_{i=1}^{n} \overset{1}{p}_i\overset{0}{q}_i \Big/ \sum_{i=1}^{n} \overset{0}{p}_i\overset{0}{q}_i\right]100 \tag{26}$$

$$=\sum_{j=1}^{m} \overset{0}{\bar{a}}_j(\overset{1}{\bar{p}}_j/\overset{0}{\bar{p}}_j)100$$

where

$$(\overset{1}{\bar{p}}_j/\overset{0}{\bar{p}}_j)100 = \sum_{i=1}^{n_j} (a_i^j)^0[(p_i^j)^1/(p_i^j)^0]100$$

The commodities may be grouped in the same sets as in the index for the two-level *CES* function. Substituting equation (26) for (25) and putting m and $n_j=2$ shows the influence of the weighting pattern.

Table 2 shows that the magnitude of biases due to the neglect of commodity substitution in the calculation of the price index may be significant. The values of the elasticities of substitution within and between groups are quite moderate; σ_j was assumed to take values of 1.00, 1.50, and 2.00, and σ was assumed to take values between 0 and 2.00. The intragroup elasticity of substitution in particular may reasonably take on values higher than those chosen. The chosen values of the price relatives also reflect quite small changes in the relative prices of commodities; for example, the price relatives of $r_x=130$ and $r_y=110$ imply that the price of x relative to the price of y has risen by 18 percent. Although a bias of 10 percent may not appear high absolutely, it means, for example, that an increase in the price level as measured by a Laspeyres index of 5 percent is in reality only 4.55 percent. Changes of this magnitude would have an important influence on wage, welfare payments, and other policies which are based on cost-of-living adjustments. Other realistic combinations of parameter values can give considerably greater or smaller biases than those reported here.

It is possible to decompose the figures of total bias in Table 2 into the two components, that which is due to the neglect of substitution among individual commodities at the lower level, and that which is due to the neglect of substitution among the commodity groups at the higher level. The first row of Table 2 shows the bias which results when there is substitution at the bottom level which is wrongly neglected but no substitution at the top level. The lower rows in the table show the bias when substitution at both levels is neglected. The differences between a figure in a lower row and the figure in the first row for the same column is the net contribution to the total bias of the neglect of top-level substitution.

One notable result emerges for all columns in Table 2. In all cases the neglect of substitution at the bottom level causes more than one-half of the total bias. This arises for two reasons. First, the values chosen of the elasticities of substitution among individual commodities at the bottom level are generally higher than those of the intergroup elasticity of substitution at the top level; the three values of σ_j are 1.00, 1.50, and 2.00, while the values of σ in Table 2 range from 0 to 2.00. Second, the formation of the sub-price indices at the bottom level as weighted averages of the component price changes for individual prices damps the relative price changes among the commodity groups, for a given set of price changes for the individual commodities. Thus studies which use aggregated price and quantity data to calculate price indices may well omit the most important source of bias even if they employ true price index forms.

These results suggest strongly that the two previous empirical studies of true cost-of-living indices by Goldberger and Gamaletsos for Greece, and Tran Van Hoa for Australia understated the bias due to the use of Laspeyres indices. First, as equation (11) reveals, the true index on the assumption that the particular form of the utility function is Stone-Geary differs from the Laspeyres index only with regard to above-subsistence expenditure. In the case of Greece the share of subsistence expenditure in the total budget s^0 used in the computation of T was 82 percent, so that it is not surprising that the study showed negligible bias (see Goldberger and Gamaletsos, p. 395); in the above sense, less than 1 percent. In the case of Australia the share of subsistence expenditure is 59 percent (see Tran Van Hoa, Table II). The bias in the above sense for the all-Australia index works out to be 7.63 percent. Comparing the Stone-Geary index with the two-level *CES* index, the Stone-Geary assumption that part of the budget must be devoted to an unchanging bundle of subsistence commodities rules out substitution bias among these purchases. However, the more important reason for believing that the bias may well be greater than indicated in these two studies is that both employed highly aggregative consumption data; five commodity groups in the Goldberger-Gamaletsos study and nine in the Tran Van Hoa study. Even if one accepts the maintained hypothesis that the utility function is Stone-Geary in these commodity groups, there may be substantial substitution among the individual food and clothing, etc. commodities within these groups. The neglect of these substitutions may mean most of the bias persists in the "true" estimates.

The same computations of bias may be made when an index other than Laspeyres is used. When a Paasche index with fixed current period weights is used in place of a true two-level mean, the qualitative behavior and magnitude of the bias may be determined from the analysis of the Laspeyres index bias. This is apparent if we rewrite the Paasche index as a weighted arithmetic mean of arithmetic means as was done for the Laspeyres index in equation (26), and rewrite the true index in terms of current rather than base period budget shares:

$$(27)\quad P = \left[\sum_{i=1}^{n} \overset{1}{p}_i \overset{1}{q}_i \Big/ \sum_{i=1} \overset{0}{p}_i \overset{1}{q}_i \right] 100$$

$$= \left[\sum_{j=1}^{m} \overset{1}{\bar{a}}_j [(\overset{1}{\bar{p}}_j / \overset{0}{\bar{p}}_j)^{-1} 100] \right]^{-1}$$

and

$$(28)\quad T = \left[\sum_{j=1}^{m} \overset{1}{\bar{a}}_j [(\overset{1}{\bar{p}}_j / \overset{0}{\bar{p}}_j) 100]^{-(1-\sigma)} \right]^{-1/(1-\sigma)}$$

At the bottom level the sub-price indices for the Paasche and true index are weighted arithmetic means and means of order $(1-\sigma_j)$, respectively. Given the current periods weights the values of P and T for given values at $(1-\sigma)$ and $(1-\sigma_j)$ may be identified with the values of T^* in Table 1 for values of $-(1-\sigma)$ and $-(1-\sigma_j)$.

What are the implications of these results for index calculation? First, it appears that the extent of the biases resulting from the use of fixed weight indices are too great to be ignored when substitutability among commodities is not low. The problem is likely to be acute when the base weights used for the index are not revised over a period of several years and relative prices diverge substantially from those of the base period.

Unfortunately, this is often the case. More frequent revisions of the weights and chaining of the resulting indices might reduce or increase the Laspeyres index (see for example Allen, pp. 387–88), but cannot give a true index for a chosen level or levels of utility. The predominance of the bias due to the neglect of substitution within commodity groups suggests we may obtain a good approximation to the true index in some cases if we use Laspeyres indices for the commodity groups and their prices, provided we calculate the sub-price indices correctly with the non-Laspeyres indices. Another possibility is the use of some other average; for example, the weighted geometric mean. The use of the geometric mean is equivalent to restricting all elasticities of substitution to unity but, in the presence of cross-substitution effects, it frequently gives estimates of the true value which are closer than restricting all to the value of zero by using constant weights (see the rows for $\sigma=1$ in Tables 1 and 2). However, if the degree of substitutability does differ among individual commodities or commodity groups a direct estimation of the true indices is preferable.

III

The use of these methods to examine true price indices for consumption commodities can be extended to incorporate leisure, multiperiod consumption, and durable goods.

When leisure is added as another commodity whose price is the wage rate per period of leisure foregone, income received from work and expenditure on commodities other than leisure are now endogenously determined. Although minimum expenditure now includes expenditure on the commodity leisure, the utility-maximizing definition of the true price index is no different from that of the previous sections.

The generalization of the model to allow for multiperiod consumption is quite straightforward if one uses the standard Fisherian model with no uncertainty regarding prices, incomes, and interest rates in each period and a fixed planning period. This model permits borrowing and saving in individual periods. The consumption of a physically identical commodity in each time period (or location) is regarded as distinct commodities, all of which enter the intertemporal utility function separately as arguments. These include durable goods with the (discounted) period rental of the commodity as the price.[8] Maximization of utility, given the prices in all periods, yields a time-path of consumption bundles and hence of expenditures in each period. For the purpose of the true price index, expenditure in a price situation is now defined as the aggregate present discounted value of this stream of expenditures and the true index is the ratio of minimum discounted expenditures for two chosen price situations.[9] All of the theorems above continue to apply.

Theorem 2 can be applied in the multiperiod model to achieve a further simplification if one is prepared to assume that U is homogeneously separable with respect to the period bundles, viz.,

---

[8] When the commodity is not rented, the quantity purchased and quantity available for use (equal to the depreciated stock plus new purchases) are no longer equal in each period. The model may include this case (see M. J. Martin).

[9] This definition differs from that of Malcolm Galatin. His two-period model departs from the standard model in that he assumes a consumer's plans for period 0 are fulfilled but that in period 1 there is an unexpected change in prices. The denominator of his true index is actual expenditure in period 1 and the numerator is the expenditure that would be required in period 1, given new prices in this period, to bring the consumer to the level of utility he would have achieved had the prices of period 0 continued in period 1. Since the prices of period 0 are neither the expected nor actual prices of period 1, this is a curious definition. The definition above is the logical extension of the single period case.

$$(29)\quad U = V(v^0(q_1^0, \ldots, q_n^0), \ldots, v^t(q_1^t, \ldots, q_n^t))$$

where the v^i are all homogeneous of degree one. The superscripts indicate the time periods of each consumption bundle. In this case consumption in each period can be treated as a composite commodity which has a price index. The allocation of aggregated discounted income among periods now depends only on relative period price indices. For example, the two-level Sato function of Section II can be interpreted as a two-period consumption model with the allocation of expenditures between the two periods at the top level being determined by period price indices. The numerical results of Section II apply immediately with the minimum expenditures and the commodity prices of both situations interpreted as discounted.

The theory of true price indices has applications in all areas of optimizing behavior. In production theory there is a true price index showing the average change in the cost of producing some commodity or fixed bundle of commodities. In some countries there are separate indices of materials cost and the cost of capital equipment. This separation of the current and capital costs of production might be justified by assuming the production function is homogeneously separable in these two groups of inputs. But in this case, as in the computation of almost all indices of prices, there are biases due to the neglect of substitution among commodities.

A Labor Theoretic Analysis of the Criminal Choice

By M. K. Block and J. M. Heineke*

> "Much of the security of person and property in modern nations is the effect of manners and opinion rather than law."
>
> John Stuart Mill
> *Principles of Political Economy*

Recently, a number of economists have applied modern choice theory to the study of illegal or criminal activities. Almost without exception, they have emphasized the similarity between the decision to commit an offense and the traditional household choice problem. As Gary Becker in his pioneering article expresses the proposition: "Some persons become 'criminals' . . . not because their basic motivation differs from that of other persons, but because their benefits and costs differ" (p. 176). Although this point is well taken, we find that a number of recent contributions do not provide an adequate framework for analyzing the costs and benefits of an important class of illegal activities. In particular, Becker, Isaac Ehrlich, and David Sjoquist summarize the consequences of time-consuming illegal activities in terms of a distribution on wealth alone without fully considering the underlying multiattribute choice problem.[1]

The commission of most offenses results in an expenditure of effort, the possibility of an increase in the individual's wealth position, and the possibility of a penalty. Aside from the penalty, the similarity between such offense decisions and labor supply decisions under uncertainty is obvious.[2] Moreover, if the penalty is a monetary payment, the analogy is precise.

Although many criminal choice problems may be viewed within an expanded labor choice framework, care must be exercised if these problems are to be interpreted in terms of strictly monetary costs and benefits. We show below that by not fully specifying their choice problems, and therefore the transformation between what is inherently a multiattribute decision problem and the wealth-only problem, Becker, Ehrlich, and Sjoquist are led to conclusions which are valid only in very special cases. In general, we show that plausible preference restrictions are not sufficient to generate unambiguous supply results, a result that should come as no surprise since it is the same situation that confronts the investigator in most household allocation problems.[3] Therefore, policy prescriptions in this area, as in the tax incentive area, do not follow from theory but rather require empirical determination of relative magnitudes.

* Associate professors of economics, Naval Postgraduate School and University of Santa Clara, respectively. We are indebted to James Sweeney, Hayne Leland, Agnar Sandmo, and Henry Demmert for their comments and suggestions. In addition, we would like to acknowledge the comments of a referee which have been most helpful in clarifying several portions of our argument. An earlier version of this paper was read at the European Meetings of the Econometric Society 1973.

[1] Michael Allingham and Agnar Sandmo, Serge-Christophe Kolm, and Balbir Singh also have papers on the criminal choice problem. But each of these papers is concerned with income tax evasion, an activity in which "labor" may be a relatively insignificant input. If this is the case, modeling the decision problem as a choice over wealth orderings is appropriate. However, for the criminal choice in general, the labor attribute will be significant and must be included in the agent's preference orderings. For this reason, most of our attention will be focused on the papers of Becker, Ehrlich, and Sjoquist who model the general criminal choice problem. Allingham and Sandmo are aware that several attributes must in general be included in the individual's decision problem and examine certain aspects of this problem in one section of their paper.

[2] See the authors (1973a) for an analysis of the labor supply decision when returns are stochastic.

We proceed as follows: First, the individual's labor-offense supply problem is formulated in terms of the underlying multiattributed nature of the problem. Next, supply responses to various parameter shifts are investigated. As would be expected, under "usual" preference restrictions these responses are ambiguous in sign. Finally, since unambiguous results have been reported in the literature, the last section and the Appendix are devoted to determining the conditions under which unequivocal supply effects obtain.

I. The Joint Supply of Labor and Offenses

In the analysis which follows we restrict our attention to property crimes, which enables us to concentrate on what George Stigler refers to as "production offenses." Specifically, we consider an individual who is confronted with two wealth generating activities, legal activity (labor) and illegal activity (theft) and denote the time spent in these activities as L and T, respectively. Hence, the individual's evaluation of his well-being at any point in time will be a function of the time spent generating wealth and the level of his wealth, i.e.,

$$U = U(\mathrm{L}, \mathrm{T}, W) \tag{1}$$

where U is the agent's von Neumann-Morgenstern utility indicator, and W represents wealth, with $U_W>0$, $U_{\mathrm{L}}<0$, and $U_{\mathrm{T}}<0$. By including the arguments L and T explicitly in U, we are provided with a straightforward means of analyzing the role of moral and ethical considerations which may constrain the work-theft decision.

The following definitions will be used:

$r \equiv$ the rate of return to legal activity
$V \equiv$ the rate of return to illegal activity
$a \equiv$ the stochastic failure, capture, or arrest rate, $0 \leq a \leq 1$
$\theta \equiv$ the number of offenses, $\theta=\theta(\mathrm{T})$ and $\theta'(\mathrm{T})>0$
$F \equiv$ the fine per offense
$\hat{W} \equiv W^0 + r\mathrm{L} + (V-aF)\theta(\mathrm{T})$, actual wealth[4]
$\mathrm{N} \equiv$ time devoted to nonmarket activity
$\bar{\mathrm{t}} \equiv \mathrm{L}+\mathrm{T}+\mathrm{N}$

Note that the penalty for an offense is specified as a fine. This penalty specification enables us to focus on an issue of central concern in this paper, the role of psychic costs in the offense decision.[5]

A. *The Model*

According to the expected utility theorem, the individual's labor-theft supply decision is determined by

$$\max_{\mathrm{L},\mathrm{T}} \int U[\mathrm{L}, \mathrm{T}, W^0 + r\mathrm{L} + (V - aF)\theta]f(a)da \tag{2}$$

subject to the condition that labor and theft levels be nonnegative. In (2), $f(a)$ is the agent's subjective probability density on the arrest rate and indicates the agent's beliefs as to the intervals in which the arrest rate is likely to lie. To facilitate comparison to the existing literature, we adopt the specification used in Ehrlich, Sjoquist, and Morgan Reynolds and fix the amount of time allocated to nonmarket activities.[6] Further, the number of offenses is assumed to be proportional to the time devoted to their production. Under these assumptions the first-order condition for a relative maxima requires that

---

[3] In particular, the agent's simple behavior toward risk contains qualitative supply implications only in highly restrictive circumstances.

[4] We use the term "actual wealth" to denote the wealth that an individual has available to meet financial obligations. It is initial wealth W^0 plus earnings or losses during the period under consideration; $\hat{W}$ is a particular value of W.

[5] While the introduction of a prison sentence would complicate the analysis, it would not invalidate the basic argument which follows. In addition, according to Becker, pp. 193–98, fines are not only the most common form of punishment, but also the most "efficient." For an analysis in which prison sentences are formally introduced into the choice problem, see Block and Robert Lind.

$$E[U_T - U_L + U_W((V - aF)\theta' - r)] \leq 0 \tag{3}$$

where $\theta' \equiv d\theta/d$T. As would be expected, when the psychic cost of effort is afforded its traditional labor theoretic role, the agent's simple behavior toward risk (*sign* U_{WW}) has no unique allocative implications.[7] Hence, Ehrlich's assertion, p. 528, that preferences toward risk and relative returns alone determine the degree of specialization will not hold in general. Only in a special case where "returns" include a strong assumption concerning psychic costs is such a statement valid.[8] In general, the time allocation between L and T will depend not only upon the agent's behavior toward risk and relative returns but also upon the relative "irksomeness" of alternative occupations.

By way of illustration, consider an individual for which $U_L - U_T > 0$ for all L, T, and W. We might say such an individual has a *preference for honesty*. If he is also risk averse, then a necessary but not sufficient condition for T>0 is that the returns to illegal activity be greater than expected costs (where costs consist of the average penalty plus legal opportunities foregone). For this condition to also be sufficient for T>0, returns must be sufficiently high to outweigh the psychic disadvantage of participation in illegal acts. In addition, increasing the certainty of arrest, increasing penalties, or increasing legal opportunities until "crime does not pay," $(V - E(a)F)\theta' - r < 0$, will deter this group of offenders. On the other hand, if the individual displays both a preference for risk and honesty, making "crime not pay" may not deter participation.[9]

II. Supply Behavior and Policy Changes[10]

In this section, we pose a number of questions concerning the supply behavior of a single economic agent. In particular, we investigate the agent's supply response to changes in (i) initial wealth, (ii) the payoff to illegal activity, (iii) the arrest rate, and (iv) the severity of punishment.

In most of the comparative static derivatives which follow, second derivatives of U appear in product expectations. This points up a well-known characteristic of stochastic models, viz., that a qualitative analysis of parameter shifts in these models often requires third derivative information concerning the agent's utility indicator.[11] The customary method of providing this information is to postulate plausible hypotheses regarding the agent's behavior toward risk as various arguments of the utility indicator change. For example, the multiattribute analog of the Arrow-Pratt absolute risk aversion function, $R \equiv -U_{WW}/U_W$, has been termed the conditional (absolute) risk aversion for wealth by Ralph Keeney. If the agent becomes increasingly willing to accept a wealth gamble of a given size as his wealth increases, *ceteris paribus*, he is said to display decreasing absolute risk aversion in wealth ($\partial R/\partial W<0$), a hypothesis we shall adopt. This restriction on the agent's preferences has been widely utilized and has led to many interesting results.[12]

---

[6] That is, $\mathrm{N} = \bar{\mathrm{N}}$, a constant.

[7] Notice that although only first derivatives of U appear in (3), a necessary condition for signing the term $EU_W(V-aF)$ is knowledge of *sign*$[U_{WW}]$. To see this note that $EU_W(V-aF) \equiv \mathrm{Cov}(U_W, V-aF) + E(U_W)E(V-aF)$ and that *sign*$[\mathrm{Cov}(U_W, V-aF)]$ depends upon how U_W *changes* with *changes* in $V-aF$ (on the average). To illustrate, consider an increase in the value of a (a decrease in $V-aF$). Now decreases in $V-aF$ cause decreases in $\hat{W}$ which in turn cause U_W to either increase or decrease depending upon whether U_{WW} is negative or positive. So if $U_{WW}<0$ then decreases in $V-aF$ cause increases in U_W and U_W and $V-aF$ move in opposite directions on the average, i.e., $\mathrm{Cov}(U_W, V-aF)<0$. Similar arguments show $U_{WW}>0$ implies $\mathrm{Cov}(U_W, V-aF)>0$ and $U_{WW}=0$ implies $\mathrm{Cov}(U_W, V-aF)=0$. In general a necessary but not sufficient condition for signing product expectations containing unrestricted random variables is sign knowledge on derivatives of one higher order than those appearing in the expectation.

[8] This point is discussed in more detail below.

[9] Risk-averse individuals with a preference for illegal activities, $U_L - U_T < 0$, may not be deterred by making crime not pay in this sense.

[10] In the discussion that follows, we assume internal solutions exist to first-order conditions.

[11] This statement is an application of the principle stated at the end of fn. 7. So, for example, a necessary condition for signing the term $EU_{WW}(V-aF) \equiv \mathrm{Cov}(U_{WW}, V-aF) + E(U_{WW})E(V-aF)$ which appears in equation (4), is *sign*$[\partial U_{WW}/\partial(V-aF)]$. That is, *sign*$[\mathrm{Cov}(U_{WW}, V-aF)]$ depends upon how U_{WW} *changes* as $V-aF$ *changes*. Hence, *sign*$[U_{WWW}]$ is needed.

A. *Wealth Effects*

A question of considerable interest to both criminologists and economists is the effect on the level of criminal activity of changes in the offender's "initial wealth." For example, would increased welfare payments have incentive or disincentive effects on the supply of offenses? To investigate this question, differentiate (3) with respect to W^0. In which case

$$\partial \mathrm{T}/\partial W^0 = E[U_{\mathrm{L}W} - U_{\mathrm{T}W} - U_{WW}((V - aF)\theta' - r)]/F_{\mathrm{TT}} \tag{4}$$

where $F \equiv EU(\mathrm{L}, \mathrm{T}, \hat{W})$.

Clearly, knowledge of the individual's simple behavior toward risk (*sign* U_{WW}) will not provide sufficient information to deduce the inferiority (or perhaps normality) of illegal activity; nor for that matter, will the combination of, say, risk aversion and decreasing absolute risk aversion. Only a priori considerations can *sign* $\partial \mathrm{T}/\partial W^0$ at this level of generality.

B. *Payoff Effects*

To our knowledge, most of the research on illegal activities has focused directly on deterrence, and hence payoff effects on the supply of these activities have been largely ignored.[13] This neglect appears even in much of the recent economics of crime literature. For example, although Becker includes "net returns" in his formulation, it is not central to his supply of offenses analysis. Certainly, any analysis of property crimes must include an examination of payoff effects as a matter of central concern. To this end, write

$$\partial \mathrm{T}/\partial V = -EU_W\theta'/F_{\mathrm{TT}} + \theta\partial \mathrm{T}/\partial W^0 \tag{5}$$

Equation (5) is the stochastic analog of the familiar Slutsky expression and is composed of a substitution effect and a wealth effect. Since F_{TT} and θ' are negative and positive, respectively, the substitution term is positive. Hence, the direction of the supply response will depend upon the wealth effect. If theft is an inferior activity, no qualitative conclusions are forthcoming.[14]

Of course, this comes as no surprise. Economists have long known that "price effects" in household decision models are ambiguous in sign. Without further preference information, the necessary condition for a positive supply response is the normality (or wealth independence) of illegal activity. Without this condition, the possibility that theft is a Giffen activity cannot be dismissed.

C. *Enforcement Effects*

In the model being investigated in this paper, uncertainty is introduced through the enforcement variable a. The payoff and penalty are both assumed to be known but the frequency of penalty imposition (the arrest rate) a is taken by the agent to be a continuous random variable, $0 \leq a \leq 1$. This specification is a generalization of the

---

[12] See, for example, Sandmo (1970, 1971), Hayne Leland (1968, 1972), Jan Mossin (1968a,b), and Block and Heineke (1972, 1973a).

[13] See Clarence Schrag, pp. 20–113, for a brief survey of the criminology literature in this area.

[14] Of course this statement remains valid a fortiori if the time allocation to nonmarket activities is endogenously determined.

Bernoulli formulation used by Becker, Ehrlich, and Sjoquist. (See the Appendix.)

The relation between the offense decision and changes in the degree of enforcement has been a topic of long-standing speculation. But because the arrest rate is a random variable there is no unique interpretation of an increase in enforcement. However, an intuitive approach is to consider changes in enforcement procedures that increase the expected number of arrests but leave all other moments of $f(a)$ unaltered. That is, we consider a "pure" increase in the arrest rate. This may be accomplished by replacing a in (3) with $a+\delta$ where δ is a mean altering, dispersion preserving parameter. Differentiating with respect to δ and evaluating at $\delta=0$ yields:

$$\partial \mathrm{T}/\partial\delta = -F(\partial \mathrm{T}/\partial V) \tag{6}$$

As we have noted, without relative magnitude information, $\partial \mathrm{T}/\partial V$ is unambiguously signed only if $\partial \mathrm{T}/\partial W^0 \geq 0$. Hence, for this class of penalties, we are able to assert unequivocally the deterrent effect of increases in the arrest rate ($\partial \mathrm{T}/\partial\delta < 0$) only by assuming the normality (or wealth independence) of illegal activity.

D. *Penalty Effects*

In the past decade we have witnessed a heated polemic concerning the effects of changes in the severity of punishment on the crime rate. Protagonists of the "liberal" position have often claimed that increasing the severity of punishment has little or no deterrent effect on the supply of offenses, while more "conservative" individuals have denounced this group as "soft on crime" and recommended increased penalties to combat growing crime rates. Although much of this argument has been couched in ideological considerations, the central question concerning the supply effects of changes in the severity of punishment is a major concern of policy makers. We now consider this question in the context of the present model.

The first-order conditions (3) indicate that the net rate of return to theft, the individual's behavior toward risk, and his "ethics," jointly determine the offense level. Hence, by examining (3) one can find several combinations of ethics and behavior toward risk which would result in zero offenses for sufficiently severe penalties. For example, if the world were comprised of risk-averse individuals who display honesty preference, $(U_{\mathrm{L}}-U_{\mathrm{T}})>0$, then the supply of offenses could be driven to zero by making F sufficiently large.[15] However, this is not likely to be possible, and if not, the question of the supply response to a change in the severity of the penalty must be formulated in terms of marginal changes in the penalty.

Since F is deterministic in the present model, the interpretation of a change in the penalty is straightforward. In fact, increases in F act as scale changes on the random variable a, decreasing expected returns and increasing the dispersion of returns. Formally,

$$\begin{aligned} \partial \mathrm{T}/\partial F = {} & E(U_W a)\theta'/F_{\mathrm{TT}} \\ & + \theta E\{a[U_{\mathrm{T}W} - U_{\mathrm{L}W} + U_{WW} \\ & \cdot((V - aF)\theta' - r)]\}/F_{\mathrm{TT}} \end{aligned} \tag{7}$$

Inspection of (7) reveals the substitution effect of a change in penalty to be negative and the wealth effect to be unsigned without further preference information. Hence, at least at the present level of generality, arguments alleging the disincentive effects of increases in the severity of punishment are not unambiguously supported by theory.

We have seen that if the multiattributed nature of the individual's decision problem is fully accounted for, then the "usual" preference restrictions concerning the individual's behavior toward risk will not provide sufficient information to sign the supply effects of increased "payoffs," "enforcement," and "penalties." The core of the problem is of course the fact that wealth effects are unsigned. And, assuming theft to be an inferior activity does not alleviate the ambiguity, since relative magnitude difficulties then arise in each case.

---

[15] See Block and Lind for a discussion of the limits of the criminal sanction.

III. Ethical Costs and Wealth: The Case of Independence

Up to this point, we have analyzed the offense decision as a generalized labor supply problem. As we have seen, the price of this generality is qualitative ambiguity.[16] In particular, the unambiguous results reported by Becker, Ehrlich, and Sjoquist are not forthcoming when the offense decision is analyzed as a general multiattribute decision problem.[17] An interesting question thus arises. What assumptions concerning the agent's utility function are implicit in the several unambiguous results reported by these authors? Or more generally, given the supply problem posed in (2), under what conditions do changes in the various components of the return to illegal activity lead to unambiguous supply responses? It is to this question that we now turn.

Becker, Ehrlich, and Sjoquist have analyzed the criminal choice using a special form of (2) in which all costs and benefits associated with criminal activity have been expressed in terms of wealth alone. That is, in their models L and T do not enter the utility function directly as attributes, but rather affect the level of utility indirectly through their effects on wealth. For example, Becker writes, costs ". . . can be made comparable by converting them into their monetary equivalent . . ." (p. 179), while Ehrlich defines the individual's wealth so that it includes ". . . assets, earnings within the period and the 'real wealth' equivalent of nonpecuniary returns from legitimate and illegitimate activity . . ." (p. 525). Or, in the words of Sjoquist: "The psychic gain is measured by that quantity of money which the individual is willing to pay to obtain the psychic gain" (p. 439). To contrast the present model with the work of these authors, we reformulate the above problem and express the psychic cost of L and T in terms of their wealth equivalents.

Formally, the problem posed in (2) may be reduced to an equivalent single attribute problem by defining a level of wealth W^* such that $U(\mathrm{L}, \mathrm{T}, \hat{W}) \equiv U(0, 0, W^*)$. Clearly, $\hat{W} - W^*$ is the wealth equivalent of L hours of legal activity and T hours of illegal activity.[18] In general, the wealth equivalent will be a function, say C, of L, T, and $\hat{W}$; i.e.,[19]

$$\hat{W} - W^* = C(\mathrm{L}, \mathrm{T}, \hat{W}) \tag{8}$$

Using (8), we may write

$$U(\mathrm{L}, \mathrm{T}, \hat{W}) \equiv U(0, 0, \hat{W} - C(\mathrm{L}, \mathrm{T}, \hat{W})) \tag{9}$$

---

[16] Again, this ambiguity persists a fortiori if the time allocated to nonmarket activities is not fixed.

[17] The only exception to this statement is the response of offenses to a change in a when $f(a)$ is Bernoulli, a result reported by all three authors. Although this result does hold after the multiattributed structure of the problem is incorporated into the model, it holds only because the arrest rate is assumed to be Bernoulli distributed. Some of the implications of assuming $f(a)$ to be Bernoulli are discussed in the Appendix.

[18] A case in which the wealth equivalent of T hours of illegal activity does not exist occurs when $(\partial W/\partial \mathrm{T})_{U^0}$ fails to exist for all L, T, and W. An individual possessing such an ethic might be said to be *absolutely honest*. In this case, one has a family of utility indicators parametric on T which are lexicographically ordered by T. Formally, let $V^{\alpha}(\mathrm{T}^{\alpha}, \mathrm{L}, W)$ represent a family of utility indicators parametric on T^{α}, where $\alpha \epsilon \Lambda$, an index set. Then absolute honesty implies $V^{\alpha_0} > V^{\alpha^*}$ iff $\mathrm{T}^{\alpha_0} < \mathrm{T}^{\alpha^*}$, for all L and W. The set $\{V^{\alpha}\}$, $\alpha \epsilon \Lambda$, is only partially lexicographically ordered since if $\mathrm{T}^{\alpha_0} = \mathrm{T}^{\alpha^*}$, then $V^{\alpha_0} \gtrless V^{\alpha^*}$ depending upon the values of L and W.

[19] A unique wealth equivalent exists (and hence the function C) iff U_{L}, U_{T}, and U_W are continuous, monotonic functions of their arguments and $U_W > 0$ everywhere.

One can analyze the choice problem at hand in terms of either the right-hand or left-hand side of (9). On the right-hand side the attributes L and T have been collapsed into their wealth equivalents, leaving the single attribute utility indicator, $U(0, 0, W^*)$. For brevity, we define $U(0, 0, W^*) \equiv \bar{U}(W^*)$. Of course, nothing has been changed since the individual's orderings over the single attribute $\hat{W} - C(\mathrm{L}, \mathrm{T}, \hat{W})$ are equivalent to his orderings over the attributes L, T, $\hat{W}$.[20] Note that the single attribute formulation treats psychic costs (benefits) as a simple subtraction (addition) from (to) wealth and hence, is the analytic justification for the approach adopted by Becker, Ehrlich, and Sjoquist in which psychic costs and returns are reduced to their monetary equivalent and then combined with monetary returns and costs. Unfortunately, none of these authors has derived his model from the underlying multiattributed structure of preferences, with the consequence that the results reported in each paper are valid only for a special case. In terms of the utility indicator $\bar{U}(\hat{W} - C(\mathrm{L}, \mathrm{T}, \hat{W}))$, their special case is equivalent to assuming the function C is independent of wealth, i.e., $C = C(\mathrm{L}, \mathrm{T})$ or $C_W = 0$.[21] We now turn our attention to several implications of this assumption.

A. *Wealth Effects* ($C_W = 0$)

As we have seen, traditional restrictions on preference orderings are insufficient to establish the effect of changes in initial wealth on the allocation of time to criminal activities. Hence the supply effects of changes in the payoff to illegal activity, the degree of enforcement, and the severity of punishment are unsigned. However, if attention is focused on the special case analyzed by Becker, Ehrlich, and Sjoquist, in which the monetary equivalent of the psychic cost of legal and illegal activity C is independent of wealth, then the wealth effect is signed and likewise are the effects of changes in the payoff, enforcement, and punishment. To see this we reformulate the supply problem given in (2) by replacing $U(\mathrm{L}, \mathrm{T}, \hat{W})$ with $\bar{U}(\hat{W} - C(\mathrm{L}, \mathrm{T}))$.[22] In which case equation (4) becomes

$$(4') \quad \partial \mathrm{T}/\partial W^0 = -E\bar{U}_{WW}[(V - aF)\theta' - r + C_{\mathrm{L}} - C_{\mathrm{T}}]/H_{\mathrm{TT}}$$

where $H \equiv E\bar{U}(\hat{W} - C(\mathrm{L}, \mathrm{T}))$.

As is obvious, the agent's simple behavior toward risk (*sign* $\bar{U}_{WW}$) provides sufficient information for signing (4′) only in the trivial case of risk neutrality, in which case the individual's time allocation to theft is invariant to changes in W^0. Generally, third derivative information will be needed.[23] If the individual is risk averse, the Arrow-Pratt measure provides the needed information. It can be shown that if this measure decreases in wealth ($\partial R/\partial W < 0$), then the numerator of (4′) is negative.[24] The crucial requirement, which is absent in the general case where $C = C(\mathrm{L}, \mathrm{T}, \hat{W})$, is that the non-linear portion of the wealth constraint be nonrandom. This is precisely the effect of making C independent of wealth. We now have

$$(10) \qquad \partial \mathrm{T}/\partial W^0 > 0$$

If the pyschic costs of effort are independent of wealth, and if the agent exhibits decreasing absolute risk aversion, then effort expended generating income via illegal activity will increase with wealth. In other words, given the widely employed and currently unrefuted hypothesis of decreasing absolute risk aversion, the Becker, Ehrlich, and Sjoquist specifications imply theft is a normal activity.[25]

---

[20] For a detailed discussion of wealth equivalence, see Block and Heineke (1973b).

[21] For example, Ehrlich's equations (1.2) and (1.3), p. 525, and Sjoquist's equations (2) and (4), p. 441, all imply that the psychic costs and benefits of both legal and illegal activity are independent of wealth. For a more detailed discussion of this point, see Block and Heineke (1974).

[22] To simplify notation in what follows, $\bar{U}_W$ will be used to represent $d\bar{U}(W^*)/dW^*$.

[23] See fnn. 11 and 7 for a discussion of this point.

[24] For proof of a formally identical proposition, see Sandmo's (1971, pp. 68–69) demonstration of the negative output effects associated with changes in fixed costs.

We now briefly reexamine the other supply effects reported above for the case where C and W are independent.

B. *Payoff Effects* ($C_W=0$)

For the case at hand, equation (5) above becomes

$$(5') \quad \partial T/\partial V = -E\bar{U}_W\theta'/H_{TT} + \theta\partial T/\partial W^0$$

The substitution effect in (5′) is positive and as we have seen under the Arrow-Pratt hypothesis the wealth effect is also positive. Hence, if psychic costs are invariant in wealth and if absolute risk aversion decreases in wealth, then the agent will unambiguously devote more hours to illegal activity as the return to these activities increases.

C. *Enforcement Effects* ($C_W=0$)

Derivative (6) above is of course still

$$(6') \quad \partial T/\partial\delta = -F(\partial T/\partial V)$$

where δ is the mean altering, dispersion preserving, additive shift parameter on the random variable a. But as has been noted, with $C_W=0$ decreasing absolute risk aversion implies $\partial T/\partial V>0$ and therefore increases in the arrest rate will produce an unambiguous deterrent effect on the supply of offenses.

D. *Penalty Effects* ($C_W=0$)

When $C_W=0$, the penalty effect reported in equation (7) becomes

$$(7') \quad \partial T/\partial F = E(\bar{U}_W a)\theta'/H_{TT} + \theta E[\bar{U}_{WW}((V-aF)\theta' - r + C_L - C_T)a]/H_{TT}$$

Since $\bar{U}_W$ and a are each nonnegative random variables, the first term in this expression is negative. In addition, it is easy to show that decreasing absolute risk aversion implies the numerator of the second term is positive.[26] Therefore, both terms are negative and we have the result reported by Becker, p. 177, Ehrlich, p. 529, and Sjoquist, p. 441: Increases in "punishment" unequivocally reduce the incentive to engage in illegal activities. Again the independence of psychic costs and wealth implicit in the Becker, Ehrlich, and Sjoquist models eliminates the ambiguity reported for the general case.

E. *Pure Dispersion Changes*

We now turn our attention to an additional and very interesting parameter shift, a shift discussed by Becker, Ehrlich, and Kolm.

The relation between the offense decision and the degree of certainty with which the penalty is administered has been debated endlessly by criminologists. Well over a century and a half ago, Sir Samuel Romilly, in a series of debates with William Paley, held that not only did certainty of punishment deter criminal activities, but also that certainty of punishment was more crucial then severity. "So evident is the truth of this maxim that if it were possible that punishment could be reduced to an absolute certainty, a very slight penalty would be sufficient to deter almost every species of crime. . . ."[27] We next determine whether the present model contains any implications concerning the deterrent effects of increases in the certainty of punishment.

---

[25] Since the time allocations to income generating activities is fixed, i.e., $N=\bar{N}$, inequality (10) implies $\partial L/\partial W^0<0$.

[26] To see this, let $Z=(V-aF)\theta'-r+C_L-C_T$ and let W_0 be that wealth level such that $Z=0$. We must show $E(\bar{U}_{WW}Za)>0$. If $Z>0$ then $aR<(aR)_0$ where $(aR)_0$ signifies that the product aR is evaluated at W_0 and hence is nonrandom. Therefore, $-Za\bar{U}_{WW}<(aR)_0\bar{U}_WZ$. If $Z<0$ the analogous argument yields the same result. Hence, $-E(\bar{U}_{WW}Za)<(aR)_0E(\bar{U}_WZ)$. But $E(\bar{U}_WZ)$ is the necessary condition for an internal maximum and must be zero. Therefore, $E(\bar{U}_{WW}Za)>0$. Note that if (a) is Bernoulli, risk aversion alone signs (7′). See the Appendix.

A widely utilized method of studying the effects of changes in the dispersion of a random variable consists of using a combination of a multiplicative and an additive parameter shift on the variable in question. The multiplicative shift "spreads" the density, while the additive shift is used to keep the mean of the variable unchanged.[28] To assess the supply effects of a change in the dispersion of punishment, we apply the additive shift parameter to a, say γ, which in turn acts as a multiplicative shift on F. The parameter γ is restricted to ensure $E(aF)$ is unchanged.[29] It is interesting to note that dispersion changes generated in this manner are formally identical to the changes in the probability of arrest "compensated" by changes in the penalty reported by Becker, p. 178, Ehrlich, p. 530, and Kolm, p. 266.[30]

Differentiating the right-hand side of (9) first with respect to T, then with respect to γ and evaluating the result at $\gamma=0$, we have[31]

$$\text{(11)}\quad \partial \mathrm{T}/\partial\gamma = -(F/E(a))\{\mathrm{Cov}\,(\overline{U}_W, a)\theta' + \theta\,\mathrm{Cov}\,[\overline{U}_{WW}((V-aF)\theta' - r + C_{\mathrm{L}} - C_{\mathrm{T}}), a]\}/H_{\mathrm{TT}}$$

Unlike the other comparative static results reported in this section, decreasing absolute risk aversion will not be sufficient to sign (11). For risk-averse agents Cov $(\overline{U}_W, a)$ is positive, but nonlinearities in "ethical costs" $C_{\mathrm{L}}-C_{\mathrm{T}}$, prevent further analysis of the second covariance term. It would seem that this term can be signed only if the function $C(\mathrm{L}, \mathrm{T})$ is linear. An individual for which this condition holds might be said to display *ethical independence*,[32] in which case it can be shown that $\partial R/\partial W<0$ implies the second covariance in (11) is positive and therefore[33]

$$\text{(12)}\qquad \partial T/\partial\gamma > 0$$

Given the preference restrictions which have been enumerated, the model supports the hypothesis that increases in the certainty of punishment will induce disincentive effects. However, this seemingly very plausible result that increases in the certainty of punishment will discourage criminal activity, a hypothesis often accepted as fact, rests upon the assumptions that psychic costs are independent of wealth and that the criminal choice problem is characterized by what Arrow has called "constant stochastic returns." In other words, the deterrent effect of "small" increases in the certainty of punishment is straightforward to establish only when the criminal choice is modeled as a portfolio problem. Thus the results concerning the certainty of punishment reported by Becker, Ehrlich, and Kolm for the case where $f(a)$ is Bernoulli, are not forthcoming in the general case.[34]

---

[27] This debate is reported in Jerome Michael and Herbert Wechsler, p. 250ff.

[28] For example, see Sandmo (1970, 1971), Leland (1972), and Block and Heineke (1973a).

[29] Formally, $dE(a+\gamma)F/d\gamma=0$ and hence $dF/d\gamma = -F/E(a)$ when $\gamma=0$.

[30] This point is also noted in Brown and Reynolds, pp. 512–13. See the Appendix for a more detailed discussion.

[31] Of course, $C_W=0$ in this derivative. If not, there is no possibility of extracting qualitative information.

[32] Formally, if $U=U(\mathrm{L}, \mathrm{T}, W)$, K is a constant and $(\partial W/\partial \mathrm{T})_{U_0}-(\partial W/\partial \mathrm{L})_{U_0}=K$, L, T, $W\geq 0$, the individual is *ethically independent*. Agents whose orderings display ethical independence have the same relative "taste (distaste) for crime" no matter what their wealth may be and no matter how involved they might be in legal and illegal activities. In other words, the agent's ethical considerations are independent of both his wealth and his participation rates in income generating activities. If $K=0$ in the definition, we might say the individual is "ethically neutral." Ethically neutral individuals find legal and illegal activity equally distasteful and in effect combine them under the heading "work." These individuals probably most adequately represent the caricature of "economic man."

[33] Define $Z\equiv(V-aF)\theta'-r+C_{\mathrm{L}}-C_{\mathrm{T}}$. We are to show $\mathrm{Cov}\,(\overline{U}_{WW}Z,a)\equiv E\,[\overline{U}_{WW}Z\,(a-\mu_a)\,]>0$. Note that $Z-\mu_Z\equiv(a-\mu_a)(-F\theta')$ and hence $E[\overline{U}_{WW}Z(a-\mu_a)]\equiv -F\theta' E(\overline{U}_{WW}Z(Z-\mu_Z)]\equiv -F\theta'[E\overline{U}_{WW}Z^2-\mu_Z E\overline{U}_{WW}Z]$. For risk-averse individuals $E\overline{U}_{WW}Z^2<0$ and if $\partial R/\partial W<0$, then $E\overline{U}_{WW}Z>0$ by (10) above. The only remaining unsigned term is μ_Z. If the individual exhibits ethical independence, the necessary condition for a nonzero supply of offenses is $\mu_Z>0$. Therefore, the term in brackets is negative and $\mathrm{Cov}(\overline{U}_{WW}Z, a)>0$.

IV. Summary

We have examined in some detail the individual's choice among two income-generating and time-consuming alternatives, one legal with certain returns and one illegal with stochastic returns. Unlike the existing literature in the area, this problem was formulated in terms of the underlying multiattributed structure of preferences inherent in the decision problem. Utilizing this basic framework and carefully specifying the relationship between the multiattribute problem and its single attribute equivalent, we have shown that the results obtained by previous authors are valid only in special cases. Most significantly, changes in (i) wealth, (ii) the payoff to illegal activity, (iii) enforcement, (iv) punishment, and (v) the degree of certainty surrounding punishment were seen to have no qualitative supply implications under traditional preference restrictions.

Simplifications which may appear to be forthcoming in a "wealth only" model are the result of a failure to fully specify the transformation between the underlying multiattribute model and its single attribute equivalent. Hence, in the area of law enforcement as in taxation, policy recommendations do not follow from theory but rather require empirical determination of relative magnitudes.

APPENDIX

The Bernoulli as Subjective Density

In the analysis above we assumed only the existence of a subjective probability distribution $f(a)$. This is a much more general approach than has been adopted in previous work. Becker's pioneering work in the area and the Ehrlich and Sjoquist extensions assume a is either 1 or 0 with $f(1)=p$ and $f(0)=1-p$; i.e., $f(a)$ is Bernoulli. This implies that the individual makes decisions as if the only possible outcomes are total failure or complete success, although it is difficult to imagine a situation in which the individual would be *either* caught for every offense *or* not caught at all. This is in contrast to the above formulation in which the "arrest rate" may take on any value between 0 and 1 and hence the individual is confronted with a continuum of failure possibilities.[35] He fails on none, on all, or on any fraction of his attempted offenses. While both Ehrlich and Becker seem to suggest that their results are forthcoming for more general densities, as the results above indicate, this is not the case.[36]

To see the implications of this density, define $W' \equiv W^0 + r\mathrm{L} + (V-F)\theta$ and $W'' \equiv W^0 + r\mathrm{L} + V\theta$ and let $f(a)$ be Bernoulli. In this case,

$$\text{(A1)} \quad EU = pU(\mathrm{L}, \mathrm{T}, W') + (1-p)U(\mathrm{L}, \mathrm{T}, W'')$$

which in wealth equivalent form is

$$\text{(A2)} \quad E\bar{U} = p\bar{U}(W' - C(\mathrm{L}, \mathrm{T}, W')) + (1-p)\bar{U}(W'' - C(\mathrm{L}, \mathrm{T}, W''))$$

Note that equation (A2) is the Ehrlich model if $C(\mathrm{L}, \mathrm{T}, W)$ is not subsumed into V and $V-F$.[37]

---

[34] To interpret $\partial\mathrm{T}/\partial\gamma$ in terms of the Becker, Ehrlich, and Kolm results, note that a is increased and F is decreased such that $E(aF)$ is constant. Since $\partial\mathrm{T}/\partial\gamma > 0$, the decrease in F has the greater effect on T. (See the Appendix.)

[35] See Heineke for further discussion of this point.

[36] For example, Ehrlich states, "Although our model has been illustrated for two states of the world, the analysis equally well applies to n states . . ." (p. 528).

[37] There does remain one minor difference between the model in (A2) and the Ehrlich formulation. Ehrlich allows for variable punishment by considering a punishment function $F(\theta)$.

$$\begin{aligned}\text{(A4)}\qquad \partial \mathrm{T}/\partial\gamma = \{&-\overline{U}_W(\overline{W})[(V\theta' - r)(1 - C_W(\mathrm{L}, \mathrm{T}, W')) + C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}, W') - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T}, W')]\\ &+ \overline{U}_W(\underline{W})[(V\theta' - r)(1 - C_W(\mathrm{L}, \mathrm{T}, W'')) + C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}, W'') - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T}, W'')]\\ &- F\theta\overline{U}_W(\overline{W})[C_{\mathrm{L}W}(\mathrm{L}, \mathrm{T}, W') - C_{\mathrm{T}W}(\mathrm{L}, \mathrm{T}, W') - C_{WW}(\mathrm{L}, \mathrm{T}, W')((V - F)\theta' - r)]\\ &- F\theta\overline{U}_{WW}(\overline{W})(1 - C_W(\mathrm{L}, \mathrm{T}, W'))[((V - F)\theta' - r)(1 - C_W(\mathrm{L}, \mathrm{T}, W'))\\ &+ C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}, W') - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T}, W')]\}/G_{\mathrm{TT}}\end{aligned}$$

The essential elements of the preference restrictions underpinning the Becker, Ehrlich, and Sjoquist models may be seen by examining but one of the above supply effects: the effect on illegal activity of a "compensated" increase in the arrest rate. A compensated increase in the arrest rate consists of an increase in the arrest rate compensated by a decrease in the penalty, so that the effect of both changes is to leave the expected punishment pF unchanged. While Becker and Ehrlich employ equal and opposite percentage changes in p and F to accomplish this compensated change, it may also be performed by simply setting

$$d(pF)/dp = F + p(dF/dp) = 0$$

and hence dF/dp is equal to $-F/p$. This latter approach has the advantage of emphasizing the relationship between compensated changes in p and the more general dispersion changes discussed above. Within the Bernoulli framework, the Becker-Ehrlich compensated change is a change in the dispersion of returns to illegal activity.

To proceed, note that

$$\text{(A3)}\quad \partial \mathrm{T}/\partial\gamma = \partial \mathrm{T}/\partial p - (\partial \mathrm{T}/\partial F)(F/p)$$

where $\partial \mathrm{T}/\partial\gamma$ is the effect on illegal activity of a mean preserving (or compensated) change in p, and $\partial \mathrm{T}/\partial p$ and $\partial \mathrm{T}/\partial F$ are the effects on T of changes in p and F, respectively. The individual's optimal level of illegal activity is obtained by maximizing either (A1) or (A2). Since we are interested in isolating the preference restrictions underpinning the Becker, Ehrlich, and Sjoquist results, it is most convenient to pose the decision problem in its wealth equivalent form, (A2). To reduce the notation, define $\overline{W} \equiv W' - C(\mathrm{L}, \mathrm{T}, W')$ and $\underline{W} \equiv W'' - C(\mathrm{L}, \mathrm{T}, W'')$. Equation (A3) may now be written as shown in equation (A4) where $G \equiv p\overline{U}(\overline{W}) + (1-p)\overline{U}(\underline{W})$. We now note that in general, and contrary to the assertions made by both Becker, p. 178, and Ehrlich, p. 530, simple behavior toward risk (*sign* U_{WW}) is not sufficient to establish the qualitative effect of a compensated change in p. That is, the sign of (A4) is not determined by sign U_{WW}—one also needs information on the properties of the "cost" function C. We now show that only in a special case is it possible to infer the sign of (A4) from the sign of $\overline{U}_{WW}$ and also to infer the sign of $\overline{U}_{WW}$ from the sign of (A4).[38]

To see this, consider the special case in which ethical costs are independent of the individual's wealth position, i.e., $C(\mathrm{L}, \mathrm{T}, W) = C(\mathrm{L}, \mathrm{T})$. Under this condition (A4) may be rewritten as follows:

$$\begin{aligned}\text{(A4')}\quad &\partial \mathrm{T}/\partial\gamma\\ &= \{[-\overline{U}_W(\overline{W}) + \overline{U}_W(\underline{W})]\\ &\quad\cdot[(V\theta' - r) + C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}) - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T})]\\ &\quad - F\theta\overline{U}_{WW}(\overline{W})[((V - F)\theta' - r)\\ &\quad + C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}) - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T})]\}/G_{\mathrm{TT}}\end{aligned}$$

Equation (A4′) is the result obtained by Ehrlich and is in fact identical to his expression for a compensated change in p except for the fact that in (A4′) ethical costs have not been aggregated into "net" returns.[39]

It is straightforward to show that the sign of (A4′) is uniquely determined by the sign of $\overline{U}_{WW}$.[40] For example, if the individual is risk averse (A4′) will be positive and a compensated increase in the arrest rate will increase the individual's allocation to illegal activities. In other words, under the condition that *ethical costs are independent of wealth*, a decrease in the dispersion of returns to illegal activities will, *when the density is Bernoulli*, unambiguously lead a risk-averse (risk-preferring) individual to increase (decrease) his supply of such activities. Crucial in this result is the specific density and the independence of ethical costs and wealth. As we have shown above, if the density is not Bernoulli and/or ethical costs are not independent of wealth, simple behavior toward risk is not sufficient to establish the effect of mean preserving dispersion changes.

---

[38] More precisely in the Becker, Ehrlich, and Sjoquist models, $\partial T/\partial\gamma \gtreqless 0$ iff $U_{WW} \lesseqgtr 0$.

[39] See Ehrlich, fn. 13, p. 530.

[40] To see this, note that $((V-F)\theta' - r + C_{\mathrm{L}}(L, \mathrm{T}) - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T})) < 0$ and $(V\theta' - r + C_{\mathrm{L}}(\mathrm{L}, \mathrm{T}) - C_{\mathrm{T}}(\mathrm{L}, \mathrm{T})) > 0$ by the first-order condition and $G_{\mathrm{TT}} < 0$ by the second-order condition. Therefore the sign of the first term on the right-hand side of (A-4′) will be determined by the sign of $\overline{U}_{WW}$. Since the sign of this term will be opposite that of $\overline{U}_{WW}$, the sign of $\overline{U}_{WW}$ uniquely determines the sign of (A-4′). In fact, with $C_W = 0$, $\partial \mathrm{T}/\partial\gamma \gtreqless 0$ iff $\overline{U}_{WW} \lesseqgtr 0$.

Monopoly Pricing and Capacity Choice Under Uncertainty

By ROBERT A. MEYER*

The analysis of pricing and investment problems for a monopoly under certainty has received considerable attention in the guise of the peak-load pricing model with notable contributions by Marcel Boiteux, Herbert Mohring, Peter Steiner, and Oliver Williamson. Inquiry into the impact of rate of return regulation under certainty has proceeded along an independent track, beginning with the well-known paper by Harvey Averch and Leland Johnson, until the peak-load and regulation issues were merged by Elizabeth Bailey.

In contrast to these analyses of monopoly behavior under certainty, models of decision making under uncertainty have generally dealt with only a single product firm and an unregulated setting. While one might argue at some length over the appropriate definition and measurement of risk, its presence obviously needs to be recognized in the process of deriving pricing and investment policies for both regulated and unregulated firms.

This paper extends the monopoly pricing and investment problem under uncertainty to the case of multiple outputs[1] and at the same time uses an alternative method for representing and analyzing the effects of risk. Since one may regard a multiple output setting as applying to the same product at different points in time, the model presented here is also a generalization of the peak-load problem to allow for stochastic demands. Another and perhaps more interesting interpretation is to consider multiple outputs as sales to different groups of customers at a single point in time. This latter interpretation will be shown to lead to a new way of viewing pricing under risk which leads to a rationale for price discrimination quite different from the traditional one under certainty. In particular, this leads to implications for differential pricing between "steady customers" vis-à-vis other customers.

Differing risk preferences of the decision maker may obviously alter the implied pricing and investment rules, but the generality and elegance of using an expected utility criterion sometimes prohibits one from obtaining clear comparisons. It will be shown that use of a chance-constrained programming formulation leads to several simplifications, both in tractability and ease of practical application.

The following discussion is developed in four parts. Section I describes the basic model to be used in the remainder of the discussion and summarizes the implied pricing and investment rules under certainty. Section II extends the discussion to incorporate uncertain demands and discusses the structure of alternative monopoly models under risk. Results are developed for the risk-neutral case using both an expected profit criterion and the expected "welfare" criterion. Section III introduces the use of chance-constrained programming as a vehicle for representing non-linear risk preferences. Section IV suggests an alternative view of pricing under risk relying on an analogy between portfolio selection and choosing prices for multiple groups of customers. A conclusion summarizes the main points.

---

* Associate professor of applied economics, University of California, Berkeley. I would like to express my appreciation to M. Bruce Johnson, John A. Carlson, Morton Kamien, and anonymous referees for helpful comments. Research support by the Institute of Public Utilities, Michigan State University, is gratefully acknowledged.

[1] Phoebus Dhrymes also considers a multiple output case, but in the Dhrymes model, prices are random and a quadratic expected utility criterion is employed.

I. Riskless Monopoly Pricing

The basic model of a monopoly firm under certainty selling to n groups of customers (or the peak-load problem with time divided into n periods) has been developed using the following set of assumptions:

A1. A demand cycle (such as a day, month, or year) is divided into n periods with a known deterministic demand, $D_i(p_i)$, $i=1, \dots, n$ which depends only on the price charged in period i; $dD_i(p_i)/dp_i<0$.

A2. The admissible set of pricing rules consists of those prices which are constants over inframarginal units *and* over individuals in the same period.

A3. The "investment problem" is simply to choose once and for all "the" optimal capacity, which is regarded as completely divisible.

A4. Production costs are composed of two separable parts: a variable cost per unit of *output per demand cycle* b, and a capacity cost of β per unit of *capacity per demand cycle* (i.e., per period).[2]

A5. The firm's objective is to choose capacity level and prices such as to maximize the sum of consumers' surplus, net revenue to the firm, and producers' surplus.[3]

Optimal pricing and investment rules for a welfare maximizing objective are obtained from

$$(1)\quad \underset{p_1, p_2, \dots, p_n, Q}{\text{Maximize}}\; W = \sum_{i=1}^{n} (p_i - b) D_i(p_i) - \beta Q + \sum_{i=1}^{n} \left\{ \int_0^{D_i(p_i)} [D_i^{-1}(x) - p_i] dx \right\}$$

subject to

$$(2)\qquad D_i(p_i) \le Q \qquad i = 1, \dots, n$$

$$(3)\qquad Q \ge 0; \quad p_i \ge 0, i = 1, \dots, n$$

with the corresponding model for a profit maximizer being the same except for the omission of the third term in the objective. Table 1 provides a comparison of the pricing and investment rules for both types of objectives.[4] The welfare maximizer always charges a peak price higher than its off-peak price, while this is not necessarily true for a profit maximizer. A

---

[2] For the deterministic setting, a static model can be linked to a dynamic model of the firm and thus provide a more explicit interpretation of the capacity cost β. Modern capital theory provides a direct link for the reversible capital model—that is, a model in which the firm may purchase or sell capital at a price c_t per unit of capacity at time t. If we let δ_t denote the amount of the capital stock at the beginning of period t, K_t that is available at the end of the period, and r_t the one-period interest rate for period t, then it has been shown by Kenneth Arrow and Dale Jorgenson that the user cost of capital in period t is $\beta_t = c_t(1+r_t) - \delta_t c_{t+1}$ per unit (ignoring taxes). The foregoing remarks are not intended to justify a reversible capital model for a public utility, since such a model may be particularly undesirable as a description of the institutional environment and capital markets in which a public utility must deal; however, this indicates part of the nature of a dynamic model of the firm for which it is formally legitimate to solve the dynamic problem as a sequence of static problems. Treating average operating and capacity costs as constants will make it possible to bring the stochastic elements into much sharper focus. In addition, assumption A4, together with the fact that demand is deterministic and the problem setting is static, removes any economic rationale for excess capacity; thus $Q = \max_i \{D_i(p_i)\}$. This point is worth noting since the introduction of stochastic demand and/or the introduction of reliability of service constraints provide an economic motivation for having optimal capacity greater than expected demand.

[3] Since production costs are constant over inframarginal units, producers' surplus is zero.

[4] In the deterministic setting, results simplify quite readily since one knows the optimal price, p_i^*, for peak periods is such that $p_i^* = D_i^{-1}(Q^*)$ where Q^* is optimal capacity.

TABLE 1—COMPARISONS OF PRICING AND INVESTMENT RULES[a]

Criterion	Peak Price	Off-Peak Price	Investment Rule
Profit Maximization[b]	$p_i = b - D_i/D_i' + v_i$	$p_i = b - D_i/D_i'$	$\sum_{i=1}^{n} v_i = \beta$
	or	or	
	$p_i = \frac{\eta_i}{(1+\eta_i)}(b + v_i)$	$p_i = \frac{\eta_i}{(1+\eta_i)} b$	
Welfare Maximization	$p_i = b + v_i'$	$p_i = b$	$\sum_{i=1}^{n} v_i' = \beta$

[a] For the profit maximizing objective the v_i are the Lagrangian multipliers for the excess demand constraints $Q - D_i(p_i) \geq 0$. The symbols v_i' denote the corresponding terms for the welfare maximizing objective. For either objective, v represents the quasi rent (or marginal revenue product of capacity) from serving the ith group or period. The symbol η_i denotes the familiar price elasticity of demand, $\eta_i = dD_i/dp_i \cdot p_i/D_i$. The term peak is used for the case where the multiplier is strictly positive; however, a zero multiplier does *not* imply "off-peak" quantity demanded is less than "peak" quantity demanded since a multiplier may be zero even though the constraint holds with equality.

[b] Peak prices are not necessarily higher than off-peak prices.

profit maximizer's off-peak is equal to or greater than the welfare maximizer's off-peak price, but the profit maximizer's peak price may be *less* than the welfare maximizer's peak price. No general statement can be made concerning a profit maximizer's optimal capacity vis-à-vis a welfare maximizer's unless one knows a profit maximizer's peak prices are equal to or greater than the welfare maximizer's *in every period* (or for all customers).

II. Monopoly Pricing Under Risk

This section develops the stochastic choice problem based on both expected profit maximization and expected welfare maximization criteria. Since risk neutrality implies the firm is indifferent to risk, a more flexible scheme for treating risk-averse settings is presented in the subsequent two sections.[5] The introduction of risk—in particular, random components in demand—requires a closer look at the structure of the decision problem. What is the objective to be? What are the decision variables? How does randomness enter into the demand relationship?

---

[5] Aside from introducing risk per se, random demand poses another problem: How is demand to be rationed if realized demand exceeds capacity? This question is directly tied to the choice of decision variables. Since many of the actual settings in which the peak-load question arises are found in firms selling air transport service, electricity, telephone, natural gas, etc., it seems most plausible to treat price and capacity as decision variables. Even for other types of firms selling to multiple groups of customers, price setting seems to be a pervasive business practice. By requiring that price and capacity be chosen *prior* to demand realization there is a possibility that actual demand at the chosen price may exceed capacity, thus raising the rationing issue. Michael Visscher in commenting on an earlier contribution by Gardner Brown and M. Bruce Johnson notes that the rationing rule adopted will affect the implied optimal prices and output. This is true, however, only when one uses a welfare criterion. Expected profit maximization or even the choice of a utility function defined on profits will not lead to such an ambiguity since only the amount the firm receives "counts" and this is received from consumers who are at least willing to pay the previously named price. How much more some consumers that were denied might have been willing to pay is not relevant. Since Visscher's random rationing scheme will not alter inferences drawn from the expected profit maximization criterion one may assume this is followed; however, to preserve comparability with the deterministic results of Steiner, Williamson, and others, and with the results of Brown and Johnson, it will be assumed output is allocated to those having the highest marginal valuations first when the welfare criterion is employed.

Both the expected profit maximization and expected welfare maximization settings are developed on the basis of the following assumptions:

B1. For each time period i demand is given by $D_i(p_i)=\bar{D}_i(p_i)+u_i$ where $\bar{D}_i$ is the deterministic (or riskless) part with $-\infty < d\bar{D}_i/dp_i < 0$, and u_i is a random part defined to take values so that $0 \leq D_i < \infty$. It is assumed that u_i is drawn from a covariance stationary stochastic process with finite variance. No specific assumption is made as to the mean of u_i.

B2. $\partial D_j/\partial p_i = 0$ for all $j \neq i$ (thus, all cross-price elasticities are zero). This is certainly in conformity with reality if one thinks of demands as corresponding to different classes of customers, for example, residential vs. commercial.

B3. Total cost is composed of two parts; a variable cost of b per unit of output and a capacity cost of β per unit of capacity. The firm may adjust output *after* demand is known, but only up to the limit imposed by capacity which must be chosen ahead of time. Long-run investment choice thus enters as an upper limit on short-run production flexibility.

B4. The random component of demand possesses a density function $g_i[\cdot]$ and a distribution function $G_i[\cdot]$ independent of prices.

B5. The quantity demanded at a given price depends on the price per unit and does not depend on the "quality" of service[6] (for example, the reliability of service).

Results at each step are contrasted with the corresponding results for deterministic setting where possible.

The objective for the expected profit maximizer[7] is

$$(4)\quad E[\pi] = \sum_{i=1}^{n} \int_{-\bar{D}_i(p_i)}^{Q-\bar{D}_i(p_i)} g_i(u_i)(p_i - b) \cdot [\bar{D}_i(p_i) + u_i]du_i + \sum_{i=1}^{n} (p_i - b) \cdot Q\{1 - G_i[Q - \bar{D}_i(p_i)]\} - \beta Q$$

The first term in (4) is expected net operating revenue when actual demand is equal to or greater than zero and equal to or less than capacity, and the second term is expected net operating revenue if actual demand exceeds capacity. The last term is capacity cost. A positive optimal level of investment requires

$$(5)\quad \sum_{i=1}^{n} \{1 - G_i[Q - \bar{D}_i(p_i)]\}(p_i - b) = \beta$$

and the corresponding pricing rule for

Since the rationing question has drawn attention to the welfare criterion, it might be worthwhile to emphasize two other inherent drawbacks. Attempting to apply such a criterion in practice requires obtaining an estimate of *marginal* demand schedules, i.e., schedules of marginal willingness to pay. Even if the correct marginal schedule is employed in the theoretical part of the analysis, the prospects for empirically determining it seem somewhat less than sparkling. A second, though related point, is that the objective function typically employed to represent "welfare" adds the firm's net revenue and the uncaptured portion of consumers' valuation of output with *equal* weights. While there is probably no such thing as a "correct" weighting scheme, still it does seem unlikely that firms would be inclined to count captured and uncaptured potential revenues on an equal footing. At the very least one can view the prospect with some degree of skepticism.

[6] For an alternative certainty model which explicitly introduces "quality of product" into a regulated framework, see James Rosse.

[7] Even stated as an unconstrained maximization problem it is by no means clear that such a formulation is a well-formed maximum problem. If the objective function is strictly concave in p_i and Q, then a unique solution exists (although these values are not necessarily guaranteed to be nonnegative). Following the literature, it is assumed that the objective function here and in subsequent formulation is strictly concave in its variables and attains its maximum for nonnegative values of the variables. Generally, such an assumption will be found to implicitly restrict other functions in the problem.

positive optimal prices is implicitly defined by

$$(6)\quad \left\{(p_i - b)\frac{d\overline{D}_i}{dp_i} + \overline{D}_i\right\} G_i[Q - \overline{D}_i(p_i)] + \int_{-\overline{D}_i(p_i)}^{Q-\overline{D}_i(p_i)} u_i g_i(u_i)du_i + Q\{1 - G_i[Q - \overline{D}_i(p_i)]\} = 0 \qquad i = 1, \ldots, n$$

Equation (5) has a natural interpretation which is a direct extension of the certainty case. Under uncertainty one does not know *in advance* which period (or group of customers) will represent a peak demand. The left-hand side of (5) represents the demand for capacity at the margin and $p_i - b$ represents the quasi rent contributed by the ith period consumers. These quasi rents are not summed directly as in the certainty case, but instead are weighted by the probability that period i is a peak period, i.e., by $1-G_i[Q-\overline{D}_i(p_i)]$ where $G_i[\cdot]$ is the probability that demand in the ith period does not exceed capacity. When demand is stochastic the sharp distinction between peak and off-peak periods disappears whereas it was a center of attention in a riskless setting.

Fortunately explicit evaluation of (6) in order to compare pricing rules is not necessary since the pricing rules for a welfare maximizer take a much simpler form. Comparisons will be delayed until the results for the welfare maximizer are developed below.

The objective function for an expected welfare maximizing firm is shown in equation (7). The first term represents net operating revenue for the firm when realized demand does not exceed capacity, the second is net operating revenue when realized demand exceeds capacity, the third is capacity cost, and the fourth and fifth terms represent the consumers' surpluses corresponding to the first two terms.

From (7) the necessary condition for a positive optimal level of capacity is

$$(8)\quad \sum_{i=1}^{n} \{1 - G_i[Q - \overline{D}_i(p_i)]\}(p_i - b) - \beta + \sum_{i=1}^{n} \int_{Q-D_i(p_i)}^{\infty} g_i(u_i) \cdot [\overline{D_i}^{-1}(Q - u_i) - p_i]du_i = 0$$

Notice that this reduces to the Brown and Johnson result for $n=1$. The third term in (8) is equal to or greater than zero for all Q and p_i. The first and last terms of (8) comprise the demand schedule for capacity for a welfare maximizing firm (at the margin) whereas only the first is used for a profit maximization firm.

Optimal prices for a welfare maximizer in a stochastic setting are found from the implicit pricing rules which satisfy

$$(9)\quad (p_i - b)\frac{d\overline{D}_i}{dp_i}\{G_i[Q - \overline{D}_i(p_i)] - G_i[-\overline{D}_i(p_i)]\} = 0 \quad i = 1, \ldots, n$$

Provided $d\overline{D}_i/dp_i$ and the third term are

$$(7)\quad E[W] = \sum_{i=1}^{n}\left\{\int_{-\overline{D}_i(p_i)}^{Q-\overline{D}_i(p_i)} g_i(u_i)(p_i-b)[\overline{D}_i(p_i)+u_i]du_i + (p_i-b)Q\{1-G_i[Q-\overline{D}_i(p_i)]\}\right\} - \beta Q + \sum_{i=1}^{n}\left\{\int_{-\overline{D}_i(p_i)}^{Q-\overline{D}_i(p_i)} g_i(u_i)\int_{p_i}^{\overline{D}_i^{-1}(-u_i)} [\overline{D}_i(x) + u_i]dx du_i + \int_{Q-\overline{D}_i(p_i)}^{\infty} g_i(u_i)\left\{\int_{p_i}^{\overline{D}_i^{-1}(-u_i)} [\overline{D}_i(x)-u_i]dx - \int_{p_i}^{\overline{D}_i^{-1}(Q-u_i)} [\overline{D}_i(x)+u_i-Q]dx\right\} du_i\right\}$$

not zero, the optimal price for the welfare maximizer is the same in each period and is equal to the marginal operating cost b. A welfare maximizer's optimal prices are equal to or less than the corresponding ones for a riskless setting. In addition, the expected profit maximizer's prices are at least as high as (or higher than) the expected welfare maximizer's in every period (or to every group of customers)—a result which is not necessarily true in a riskless setting.

Since the optimal stochastic price of b holds for all periods, one obtains the Brown-Johnson result for $n=1$ as a special case. Brown and Johnson's conclusion that the firm's net revenue will be negative regardless of which (positive) level of capacity is chosen thus carries over to multiple demand groups also. Inducing a firm to follow a behavior rule which leads to such an implausible result may be yet another argument for ignoring such a "welfare" choice criterion, but there is an element omitted from the Brown and Johnson argument which may rectify the pricing aspect of the problem. While it is clear that an expected profit maximization criterion ignores risk aspects, the use of an expected welfare criterion does also. This additional part of the problem is developed in the next section.

III. Pricing With Risk Limitations

The earlier formulation of the expected welfare maximization model by Brown and Johnson for a single period led to two major conclusions: 1) optimal price equals marginal (and average variable) cost, thus a firm's net profits will always be negative; and 2) stochastic optimal capacity exceeds capacity in the corresponding deterministic setting. While the first conclusion is reached under fairly general conditions employing an additive random error term, the second conclusion was developed only for the case of a linear demand function. For all of their results Brown and Johnson employ a risk neutral criterion, thus the burden of any inherent risk falls on consumers and/or stockholders. In commenting on the Brown and Johnson formulation, Ralph Turvey (1970) emphasized that in a practical situation price must necessarily be specified prior to knowing what actual demand will be and that such prices must be chosen sufficiently high to meet specified standards of system reliability.

These observations point to a more practical way of structuring the problem by introducing chance-constrained programming. Aside from its practical aspects, a chance-constrained programming formulation allows one to directly introduce a "reliability of service" or risk constraint and analyze the effects of certain types of risk-averse behavior without the explicit introduction of a utility function. In addition, it provides a formal basis for analyzing the issue raised by Brown and Johnson (1970) when they state: "To price so high that there is rarely (never?) excess demand implies persistent excess supply (idle capacity) and an *ad hoc* decision by the public utility to remove the risk of failure. We might have more confidence in such a policy if it was derived from an optimizing model" (p. 490). It will be shown that such a price and investment policy by a firm may be far from *ad hoc*—in fact, it is optimal since the degree of failure risk is not necessarily a parameter subject to choice by the firm. Reliability of service or quality standards are frequently specified exogenously by regulatory agencies.

A chance-constrained formulation admits a clearly tractable solution which requires very few specific assumptions in order to determine the qualitative effects of a stochastic setting. An original problem is appended with a set of probabilistic constraints of the form

$$(10)\quad Prob\,\{D_i(p_i) > Q\} = 1 - G_i[Q - \overline{D}_i(p_i)] \leq \epsilon_i > 0, \quad i = 1, \ldots, n$$

where Q is capacity.[8] Constraints of this form would appear to be the natural extension to a stochastic setting of the constraints used in a riskless setting (see equation (2)), but prior work on choice under risk has not included this element.

A firm may price *as if* demand is not random by using an augmented demand schedule which satisfies (10). This is perhaps more easily indicated in a diagram. A new demand schedule $\tilde{D}_i$ is constructed in such a manner that, for each price, constraint (10) is satisfied (Figure 1). To gain some impression of the qualitative effect of ignoring such constraints, suppose Q^0 is the deterministic optimal capacity and one changes *only* prices in order to meet the risk constraints. Periods in which demand is relatively inelastic will require fairly substantial increases in price while periods with more elastic demands will require smaller price increases. In either case, it is clear that prices in each period must be raised above those that would prevail in the deterministic case, p_1^0 and p_2^0. In general, prices found in this manner will not, however, be the stochastic optimal prices, but such prices are the *minimum* prices consistent with the risk constraints for any given level of capacity. If the probability densities are symmetric about their mean, then the optimal deterministic prices p_1^0 and p_2^0 would imply a 50 percent risk of "system failure" in each period!

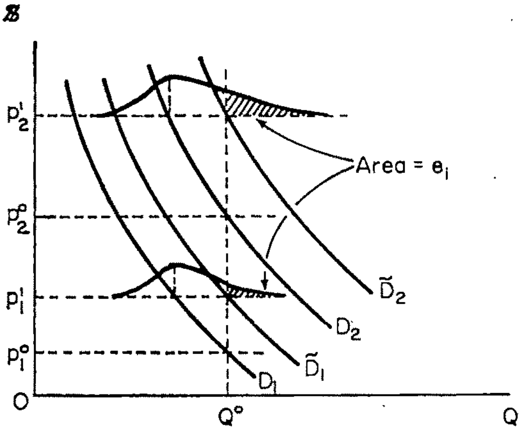

FIGURE 1

The smaller one sets ϵ_i (i.e., the smaller the risk of excess demand permitted), the larger will be the associated price increases. Solving for a price policy subject to (10) meets the criticism raised by Turvey (1968) against omission of a stochastic element: ". . . the price in any period should be such that the mean expectation of demand is *less* than available capacity. . . . This dimension of the optimal price and capacity problem has been ignored by most authors" (p. 105). The variance of demand at any price may, of course, also be dependent upon price and may be different between periods without changing the character of the solution for a given level of capacity. In a similar manner, nothing basic is altered by allowing asymmetric probability distributions.

The most straightforward analysis of the effect of imposing risk or quality constraints is probably to use the optimal solution for prices and capacity in the unconstrained stochastic setting as a refer-

---

[8] Implicitly the constraints in this form assume all demand covariances are zero and $G_i[0]=0$. The probabilistic contraints can also be written in an equivalent riskless form:

$$Prob\,\{D_i(p_i) > Q\} \leq \epsilon_i$$

is equivalent to

$$Prob\left\{\frac{D_i(p_i) - \overline{D}_i(p_i)}{\sigma_i} > \frac{Q - \overline{D}_i(p_i)}{\sigma_i}\right\} \leq \epsilon_i$$

which is satisfied by

$$Q \geq \overline{D}_i(p_i) + N_i\sigma_i$$

where N_i is the number of standard deviations above the mean, $\overline{D}_i(p_i)$, needed to reduce the area in the upper tail of the distribution to ϵ_i.

ence point. Since the objective function cannot achieve a higher value when the constraints are added, a firm seeks to meet the constraints with the smallest (possibly zero) reduction in the objective function value. The firm has at its disposal two instruments—change prices or change capacity—and both instruments have costs attached. One could meet a reliability constraint by increasing capacity alone, which would cost β per unit, or by raising prices, which would "cost" the marginal revenue foregone. The economically optimal response will be to change prices alone provided there is a set of price changes which have a total marginal revenue loss of less than β; otherwise, some combination of price changes and a change in capacity will be necessary to meet the constraint.

Maximization of expected profits or expected welfare subject to the risk constraints does not imply risk neutrality. Introduction of the risk limitations simply implies firms are risk neutral over the sets of prices and output which meet or stay within the risk limits. Reducing the ϵ_i is essentially equivalent to decreasing the degree of excess demand risk embodied in the resulting price and output choices. Although this is a less general approach than using the expected utility criterion employed by Hayne Leland, it is more tractable.

Basic results using the chance-constrained formulation are obtained by appending constraints (10) to (7) for the expected welfare criterion or to (7) after omitting the last two terms for the expected profit criterion. The investment rule (i.e., necessary condition) for an expected profit maximizer is

$$\text{(11)} \quad \sum_{i=1}^{n} \{1 - G_i[Q - \bar{D}_i(p_i)]\}(p_i - b) - \beta - \sum_{i=1}^{n} \lambda_i g_i[Q - \bar{D}_i(p_i)] = 0$$

Assuming the feasible set defined by (10) is convex, the multipliers associated with each constraint, λ_i, are nonpositive and thus the last term in (11) is nonnegative. Optimal constrained capacity is thus equal to or greater than optimal unconstrained capacity for an expected profit maximizing firm when compared at the *same* set of prices.

A comparison between price and capacity in the constrained versus the unconstrained setting can be sketched for the case $n=1$ when G is concave and strictly increasing and $\bar{D}$ is convex, since G is then concave in Q and p and the set $\{(Q, p); G[Q-\bar{D}(p)] \geq 1-\epsilon\}$ is convex. The combinations of Q and p along the lower boundary of this set form an iso-risk contour. Figure 2 indicates the nature of the feasible set, the iso-expected profit coutours, and an example of a possible solution where the subscripts refer to constrained (C) and unconstrained (U) stochastic solutions.

The negative of the multipliers on the risk constraints measure the implicit economic price (per unit) of risk reduction —essentially the maximum insurance premium for risk removal. As ϵ_i decreases, constrained expected profits decrease over their risk-neutral level which simply re-

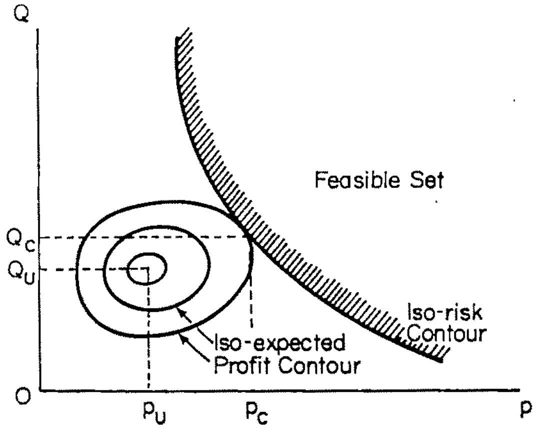

FIGURE 2

flects the fact that the firm would have been paid for assuming risk. The real cost of the risk undertaken "by the firm," however, might well be borne by customers who cannot satisfy their demand while it is the firm who stands to reap any potential benefits (apart from goodwill loss). Obviously one needs a more elaborate problem structure to develop the concept of optimal sharing of risks between the firm, consumers, and perhaps shareholders as well.

For the expected welfare criterion[9] subject to the risk constraints, one obtains the investment rule

$$(12)\quad \sum_{i=1}^{n}\{1-G_i[Q-\overline{D}_i(p_i)]\}(p_i-b) + \sum_{i=1}^{n}\left\{\int_{Q-D_i(p_i)}^{\infty} g_i(u_i) \cdot[\overline{D}_i^{-1}(Q-u_i)-p_i]du_i\right\} - \beta - \sum_{i=1}^{n}\lambda_i g_i[Q-\overline{D}_i(p_i)] = 0$$

Comparison of the optimal prices under constraint with those which would prevail without constraint indicates the prices for the expected welfare maximizer must be equal to or greater than those when no constraints are imposed. This implication follows from the fact that the unconstrained prices were all equal to b and it is never optimal to sell at less than minimum average variable cost. The optimal pricing rule is given by

$$(13)\quad p_i = b - \lambda_i g_i[Q-\overline{D}_i(p_i)] / \{G_i[Q-\overline{D}_i(p_i)] - G_i[-\overline{D}_i(p_i)]\}, \quad i = 1, \ldots, n$$

The term in braces represents the probability that actual demand is equal to or greater than zero but does not exceed capacity. With at least one constraint binding, a higher price using risk constraints implies capacity could be reduced over what would have been required to meet the constraint while charging a price of b.

IV. Risk-Adjusted Price Differentials

The discussion of both the riskless setting and pricing in a risky setting, but without risk constraints, focuses the main attention on pricing and investment rules which are "efficient" in the traditional economic sense. Once one has added risk constraints as in Section IV, a second type of efficiency suggests itself: risk efficiency.

The variance of aggregate demand depends on the prices charged each set of customers since these will alter their contribution to total demand. In addition, the variance of demand may change with price for any class of customers or there may be covariances between the demands of various customers. From basic probability rules the variance of total demand is the sum of the variances of each individual demand plus twice the sum of each pair of covariances. The possibility this presents is analogous to a portfolio selection problem. The variance of aggregate demand, and thus total output as well as profit or revenue risk, may be altered by the *mix* of prices. This suggests a rationale for price discrimination which is entirely different from the traditional one (see Kahn, p. 142).

Once one focuses on the effect on profit or total output variability associated with pricing choices one can find an immediate reason for the apparent dependence of optimal pricing rules on the way in which randomness is introduced. In an earlier exploration of the effect of demand uncertainty on monopoly pricing in riskless versus risky settings, Samuel Karlin and Charles Carr noted that: "The optimal price under multiplicative uncertainty is always greater, and under additive uncertainty always less, than the optimal price set in the equivalent deterministic monopoly models" (p. 160). In both their dynamic and one-period formulations, demand was the only random element. No explanation for this apparent sensitivity of the conclusions to model specification is offered by either Karlin and Carr or in subsequent analysis.

---

[9] It was suggested to me by Morton Kamien and also noted by Edwin Mills that a "correct" objective which is purported to measure "welfare" should include measures of product quality in the objective function. When included in the objective, "quality" could be under control of the firm as in Rosse.

When one adds the risk-efficiency notion, a partial explanation for these results emerges.[10] The variance of total revenue in the additive error model is[11]

$$(14)\qquad Var\,[TR] = \sigma^2 = \sum_{i=1}^{n} p_i^2\, Var\,[D_i(p_i)] = \sum_{i=1}^{n} p_i^2\sigma_i^2$$

where $D_i(p_i)=\bar{D}_i(p_i)+u_i$, $E[u_i]=0$, $E[u_i^2]=\sigma_i^2$. Since prices are the objects of choice one would obviously like to choose these so that (14) is a minimum for a given level of expected profits. The effect of altering the ith price is

$$(15)\qquad \frac{\partial\sigma^2}{\sigma p_i} = 2p_i\sigma_i^2 > 0$$

Thus it is easy to see that total risk decreases as one decreases prices in the additive case. When one moves from a riskless setting to a risky one, risk is lowered by lowering prices over the corresponding riskless ones.

In contrast, the multiplicative error model (i.e., $D_i(p_i)=u_i\bar{D}_i(p_i)$, $E[u_i]=1$, $Var[u_i]=\sigma_i^2$) also has an associated total revenue (or profit) risk element given by

$$(16)\qquad Var\,[TR] = \sigma^2 = \sum_{i=1}^{n} p_i^2\bar{D}_i^2(p_i)\sigma_i^2$$

Changing prices here also affects total profit risk.

$$(17)\qquad \frac{\partial\sigma^2}{\partial p_i} = 2p_i\bar{D}_i^2(p_i)[1+\eta_i]\sigma_i^2$$

where $\eta_i=p_i/\bar{D}_i\cdot d\bar{D}_i/dp_i$. Since $\eta_i<0$ the term in brackets is generally negative, thus risk is decreased by increasing prices when one moves from a riskless world to one characterized by multiplicative demand uncertainty.

Risk-efficient pricing can be characterized quite clearly in terms of the familiar mean-variance portfolio model. For every level of expected profits one defines the associated risk-efficient price set as the set of prices such that the variance of total profit is a minimum. The need for such an additional efficiency concept seems rather clear since a firm faced with selling multiple products (or to multiple classes of customers) could raise the same level of total revenue from a wide array of pricing choices along its iso-revenue surfaces, but even though total revenue remained constant, total risk would not.

When the σ_i^2 are different, then (even though they do not depend on price) the choice of different price sets changes the proportions of total demand (i.e., the proportions of each asset in the portfolio); thus total risk changes. For the perfectly competitive firm even though there exist iso-expected profit surfaces reflecting price/risk choices, the firm cannot avail itself of such tradeoffs since it acts as a price taker. Such tradeoffs are available to a monopolist.

The risk-constrained structure of the problem might be reformulated in terms of total profit risk rather than excess demand risk which brings out a risk premium facet to an optimal pricing structure. Assume a firm wishes to maximize expected profits, but with an upper limit $\bar{\sigma}^2$ on the variance of total profits:

---

[10] Since Karlin and Carr use only an expected profit criterion, their results do not arise from the risk aspect of pricing emphasized here.

[11] This and the following expressions for total revenue variance assume demand covariances are zero. In addition, the variance in demand is used in each expression which implies production is adjusted within a given period to meet realized demand. If production and/or capacity must be chosen ahead of time, sales variance replaces demand variance in each expression and in addition sales variance will not be independent of price.

$$\text{(18)} \quad \underset{p_1,\ldots,p_n,Q}{\text{Maximize}}\ E[\pi] = \sum_{i=1}^{n} \int_{-\bar{D}_i(p_i)}^{Q-\bar{D}_i(p_i)} g_i(u_i)[\bar{D}_i(p_i) + u_i]du_i + \sum_{i=1}^{n} (p_i - b)Q\{1 - G_i[Q - \bar{D}_i(p_i)]\} - \beta Q$$

subject to

$$\text{(19)} \qquad Var\ [\pi] \leq \bar{\sigma}^2$$

$$\text{(20)} \quad p_i \geq 0, \quad i = 1, \ldots, n\ Q \geq 0$$

The necessary condition for optimal prices from (18)–(20) consists of equation (6) plus a second term

$$\text{(21)} \qquad -\lambda \frac{\partial\, Var\ [\pi]}{\partial p_i} \qquad i = 1, \ldots, n$$

where $\lambda \geq 0$ represents the marginal profit for a small change in total variance at the constraint boundary. The term in (21) measures the economic cost of the marginal risk contributed by the ith group of customers. An optimal structure of prices under risk will obviously contain differences which reflect differences in the contributions each class of customers makes to total risk. Those with stable demands may contribute little or nothing to total risk and thus their prices will in general be lower, while those with unstable demand will be required to bear a risk premium which is essentially the insurance premium they must be willing to pay for exercising a demand option on capacity. The foregoing provides a partial explanation for the practice of offering special terms to "steady" customers, i.e., ones with low demand variance.

The presence of a risk-efficient aspect to pricing means one must proceed with special caution in attempting to infer whether price discrimination is present by a comparison of prices and the concept of marginal cost reckoned in traditional riskless setting.

V. Conclusion

This paper has presented a set of results for a monopolist's optimal choice of pricing and investment policy under both riskless and stochastic conditions. The riskless results were, of course, only included for completeness. Although the stochastic results are based on the additive error model, the results obtained include the special case suggested by Brown and Johnson, but do not require specific assumptions about either the demand function or about the probability distribution for the random component.

An optimal pricing/capacity choice policy will generally imply capacity is *not* fully utilized all of the time. This is not inefficiency, but rather is the optimal response on the part of a firm which seeks to limit risks. While the argument suggested by Averch and Johnson implies excess investment may be sought by a regulated firm for less pristine motives, *apparent* overengineering or *apparent* excessive investment may be simply an optimal economic decision when the firm must meet high reliability standards for the service it provides. Such a decision is not necessarily inefficient once one realizes that two efficiency conditions must be satisfied—one stemming from the traditional riskless economic setting and a risk-efficiency condition which emerges only under uncertainty.

The concept of risk efficiency in pricing and output choice is more general than the demand uncertainty case analyzed here. When applied to demand uncertainty where only total revenue (or net operating revenue) is the random component of profits, several interesting interpretations emerge for the role of prices in altering risk. An economic interpretation of two earlier results comparing riskless and risky pricing rules are seen to follow naturally from introducing the notion of risk-efficient pricing. In addition, one finds that the stochastic nature of demand may provide a rationale for price discrimination which is quite different from the traditional riskless one, since altering the "mix" of prices over classes of customers can change profit and/or excess demand risk.

Dynamic Monopsony and Structural Change

By MARTIN NEIL BAILY*

This paper examines at the microeconomic level the assumption that the rate of change of the labor supply to a firm depends on the wage paid by the firm (relative to the rest of the economy). The firm is, therefore, a dynamic monopsonist. First, the behavior of a single firm is considered and its response in terms of the optimal wage path to different product prices. Second, an industry of N such firms is analyzed with a static product demand, and the convergence of such an industry to stationary equilibrium is shown. Third, the assumptions are changed so that instead of operating in a static environment, the industry experiences changing demand, changing labor productivity, and a rising wage in the rest of the economy. In the growing environment the model predicts a pattern of wage differentials in response to steady-state trends. An additional feature of the model is that it is assumed that there is some minimum wage such that if the firms offer less than this all its workers quit. This restriction introduces the possibility of layoffs as an optimal policy by the firm. This is of interest since the monopsony assumption has been criticized (for example by Herschel Grossman) on the grounds that layoffs are excluded.

The idea of dynamic monopsony is not new. Earlier versions of this model were developed some time ago based in part on verbal discussions of the idea from a number of sources (for example, Paul Samuelson's text, p. 554). Edmund Phelps and Sidney Winter, Dale Mortensen, and other search theorists have used dynamic monopoly and monopsony assumptions to examine questions of inflation and unemployment. It should be emphasized that the model presented here takes macro variables such as the overall unemployment rate and the price level as fixed.

I. The Monopsonistic Firm

Consider a single firm which has an initial allocation of labor $L^s(0)>0$. The labor supply conditions it faces are given by:

$$\frac{DL^s}{L^s} = g(w) \tag{1}$$

where $g' > 0,\ g'' < 0,$

$$g(w) \rightarrow -\infty \text{ as } w \rightarrow w_{min} > 0$$

w is the money wage offered by the firm, but since we are taking overall conditions in the economy as constant, we can take w as the wage offer by this firm relative to the rest of the economy.[1] The specification has a certain amount of inherent plausibility, given the existence of mobility costs in the labor market. If the wage is low not all workers quit right away, but over time quits exceed hirings and the available labor supply declines. If the wage is high, quits are low and new workers are attracted to the firm. Recent literature has emphasized the informational and search costs involved in labor mobility.[2] As well as this, one would expect that even if the pattern of wages were known, the costs and possible disutility of relocation plus the cost of learning the new job would mean that the response to wage differentials would occur over time.

Brainard, the members of the Harvard-MIT mathematical economics seminar, and the managing editor and referee for many helpful comments. I retain responsibility for error. This is a considerably revised version of part of my 1972 MIT doctoral dissertation. Financial support from the Canada Council is acknowledged.

[1] Later we allow the general level of wages in the rest of the economy to be rising. This makes g shift over time.

It is specified that the *rate* of growth or decline of the labor supply depends upon the wage. This means that for a given w, a large firm will lose or gain a proportionally large number of workers. It seems plausible that when w is low then a proportion of the work force will decide to quit during any given period. It is also likely that the larger the firm the greater the number of workers who will hear about jobs from workers already employed or who will just turn up to see what opportunities are available. It would be wrong to disguise, however, that there is mathematical expediency involved also. The analysis could be made with a more general form, but it would make things much more awkward.

A more important limitation of the form used is that it embodies static expectations. Workers respond to the current wage. Parts of this paper will be concerned with cases where the static expectations are fulfilled. Whenever we consider a path of w which varies over time then the assumption becomes stronger. One can take the assumption of concavity of $g(w)$ as a proxy for a certain type of worker expectation. If the wage is increased from a low starting point, workers think the increase is more likely to persist than if it is increased from a high starting point; hence decreasing returns to successive wage increases. The concavity assumption is important for sufficiency of an optimum and for stability.

The production conditions for the firm are described by a constant returns production function.

$$X = F(K, L) = Lf(k), \qquad k = K/L, \qquad \frac{\partial F}{\partial L} > 0, \qquad \frac{\partial F}{\partial K} > 0, \qquad F \text{ concave}, \qquad F(K, 0) = 0 \tag{2}$$

where X is the output of the firm, K is the amount of capital rented, and L is the number of man-hours of labor services used.[3] In order to focus attention on the implications of the dynamic monopsony, some simple assumptions are made about the product and capital markets. The firm is allowed to rent as much capital as it wishes at a constant rental rate ρ. Therefore K is freely adjustable. On the product side it is assumed that the firm can be assumed, at least as an approximation, to be a price taker.[4] While alternative assumptions could well be made, the above has the advantage that we can examine in a straightforward way how a firm adjusts its wage in response to different values of the price it faces.

The firm, therefore, chooses values of its control variables capital, labor, and the wage to maximize the present value of its profits:

$$\max_{K,L,w} \int_0^\infty e^{-rt}[p(t)F(K, L) - wL - \rho K]dt \tag{3}$$

$$\text{subject to} \quad L \leq L^s, \quad DL^s = g(w)L^s, \quad L^s(0) \text{ given}, \quad L \geq 0, \quad K \geq 0$$

---

[2] See, for example, George Stigler, John McCall, and in particular Mortensen who gives a detailed search model that leads to a labor supply like (1). Other types of mobility cost and the effect of workers forming expectations of future wages are discussed by the author in an earlier paper.

[3] There is a complication that has been ignored. The firm can raise the number of hours worked per employee by paying overtime wage rates. A standard work week per employee is assumed here.

[4] The equilibrium of the industry including the possible entry and exit of firms is discussed in Section III.

The only state variable is L^s, the supply of labor to the firm. If on the optimal path we have $L<L^s$ then the firm is not using all the labor which offers itself. This corresponds to a layoff or a complete shutdown. This possibility is dealt with below. Consider first, therefore, the case $L=L^s$, $K>0$, and $L>0$. This simplifies the problem. The firm sets the wage and the amount of capital it wants and accepts the available labor supply. The necessary maximizing conditions are:[5]

$$(4)\qquad p(t)\frac{\partial F}{\partial K}=\rho$$

$$(5)\qquad -L+\lambda g'(w)L=0 \quad \text{or} \quad \lambda=1/g'(w)$$

$$(6)\qquad D\lambda=r\lambda-p(t)\frac{\partial F}{\partial L}+w-\lambda g(w)$$

plus the transversality conditions:

$$(7)\qquad \lim_{t\to\infty} e^{-rt}\lambda(t)\geq 0 \quad \lim_{t\to\infty} e^{-rt}\lambda(t)L(t)=0$$

and $L(t)$ must also satisfy the labor supply condition (1). Equation (4) says that the value of the marginal product of capital is always equated to the rental rate on capital. This is not surprising given the assumption of costless capital adjustment. The conditions determining the wage path are necessarily somewhat more complicated. The term $g'(w)$ is the marginal effect of a wage change in inducing more rapid growth of the available labor supply. The larger is $g'(w)$, the more responsive is the labor supply. The inverse of $g'(w)$ is equal to λ (equation (5)) which is the shadow price of the constraint, i.e., the cost to the firm of adding one more worker. Equation (6) then says that the cost λ of a marginal worker is just equal to the benefit to the firm of the marginal worker. To see this, multiply (6) through by the factor e^{-rt} and then integrate to obtain:

$$(8)\qquad \int_0^\infty e^{-rt}[r\lambda-D\lambda]dt=\lambda(0)=\int_0^\infty e^{-rt}\left[p\frac{\partial F}{\partial L}-w+g(w)\lambda(t)\right]dt$$

Hence the wage is set so that the shadow price λ of an extra worker now is just equal to the present value of the benefit—made up of two parts. First, there is the excess of the marginal product over the wage. Second, there is a term that is zero whenever the wage is set to maintain a constant labor supply $[DL^s/L^s=g(w)]$, is positive whenever the labor force is expanded, and negative whenever there is a contraction. If it is planned to expand the labor force in the future, then an extra worker hired now is valuable because he makes it easier to hire future workers (for example, by telling potential workers about the high wage available). If it is planned to contract the labor force in the future, then we must make a subtraction from the present value of the excess of product over wage because the worker hired now may be among those who quit later, so his product does not accrue for the full time.[6] Since by assumption, $g(w)$ is concave and $F(K, L)$ is concave, the necessary conditions are also sufficient for a maximum, and a path satisfying these conditions will be optimal for the problem as originally stated in (3) unless a shutdown or layoff is better.

II. Properties of the Optimal Path

Since the production function is constant returns and well-behaved, the marginal products depend only on the capital-labor ratio k and are monotonic functions of this argument. Equation (4) therefore determines $k(t)$ as a function of $p(t)$ for a given rental rate ρ. If we then substitute (4) and (5) into (6), we obtain:[7]

---

[5] The standard reference is L. S. Pontryagin et al. The exposition in Kenneth Arrow and Mordecai Kurz is also helpful. Some interpretation of the conditions is given here for the sake of clarity, but it is kept fairly brief because at this point much of the ground is familiar from Mortensen, pp. 184–86.

[6] Strictly speaking, since the variables are all continuous and nonstochastic, the mathematics say that some fraction of any workers hired now will quit later.

$$(9)\quad p(t)\frac{\partial F}{\partial L} = h(p(t)) = w + \frac{r}{g'(w)} + \frac{g''(w)Dw}{[g'(w)]^2} - \frac{g(w)}{g'(w)}$$

The function h is the value of the marginal product of labor evaluated at the optimal capital-labor ratio. It depends only on current price (since k is freely adjustable) and is a monotonic increasing function of this argument. This is easy to see since when price is high, (4) tells us that k is also high and so the marginal product of labor is high. It is worth keeping the definition of $h(p(t))$ in mind for the subsequent discussion.

Some properties of the optimal wage path determined by (9) will now be derived. Proofs of the results are in the Appendix. In general, the wage set at any instant depends upon the future path of the product price. If the firm has perfect foresight there is no problem, but more realistically we think of $p(t)$ as the expected path of the price. This, of course, still abstracts from problems of attitude towards risk. The point at which the function $g(w)$ crosses the axis is an important reference point for the path. Define $\bar{w}$ by $g(\bar{w})=0$, *so* $\bar{w}$ *is the wage the firm must pay in order to just retain the same size work force.* It is tempting to assume immediately that $\bar{w}$ must be the wage prevailing in the rest of the economy (if the total labor force is constant) for then if all firms pay the same wage none of them gains or loses workers. The general equilibrium properties of models with search or labor mobility are quite tricky, however, and so, depending upon the nature of the mobility process and on how tight or loose the overall labor market conditions are, $\bar{w}$ may in general be above or below the economy average wage.[8] This model is of partial equilibrium, however, and presumably *there is some overall condition of the labor market such that* $\bar{w}$ *is the economy average wage.* Although it is not essential to assume this neutral case, it is convenient to do so when interpreting the results.

The first feature of the firm's decision we consider is under what circumstances will the firm be content to keep its labor force constant.

PROPERTY 1. *There is a unique price* $\bar{p}$ *that is consistent with stationary* w, L, *and* K *on the optimal path.* This property follows from (9) and the fact that $h(p)$ and $g(w)$ are monotonic. Clearly $\bar{p}$ the price which causes the firm to keep its labor force constant is going to be determined by the size of $\bar{w}$ the necessary wage to achieve this constancy. In fact $\bar{p}$ and $\bar{w}$ are related by:

$$(10)\qquad h(\bar{p}) = \bar{w} + r/g'(\bar{w})$$

The stationary solution is similar to the result one would obtain from a static monopsony assumption. If there were a static rising supply curve of labor then we would have the analogous equation:

$$(11)\qquad h(p) = w + w/E$$

where E is the elasticity of labor supply. The implicit elasticity of labor supply in (10) is $\bar{w}g'(\bar{w})/r$.

If the price is constant over time but not equal to $\bar{p}$ then the optimal path will be to pay a constant wage provided the price lies within a certain interval. The firm cannot pay less than w_{min} without losing all its workers. There is a price, p_{min}, such that any constant price below this will cause the firm to shut down rather than incur the loss that would follow from paying any wage above w_{min}. If

---

[7] Since the production function is assumed to have constant returns and the labor supply condition determines the rate of change of L, equation (9) is independent of $L(0)$. This means the optimal wage path is independent of the initial condition.

[8] This point is made with respect to Phelps and Winter by William Nordhaus. In a general equilibrium context it is presumably not even valid to consider just the first moment of the distribution of wage offers by other firms, but here this distribution is taken as given.

$$h(p_{min}) = w_{min} \tag{12}$$

where w_{min} is given in (1), then any constant price below p_{min} must lead to loss or to shutdown. There is a maximum price set by the necessary conditions. If the price is too high, the integral (8) does not converge.[9] We require $r > g$, so that p_{max} is given by:

$$h(p_{max}) = w_M \tag{13}$$

where $w_M = g^{-1}(r)$

PROPERTY 2. *For any constant price* $\tilde{p}$ *such that* $p_{min} < \tilde{p} < p_{max}$ *there is a unique optimal wage path. This path is to set a constant wage* $\tilde{w}(\tilde{p})$ *where* $\tilde{w}$ *and* $\tilde{p}$ *are related by:*

$$h(\tilde{p}) = \tilde{w} + [r - g(\tilde{w})]/g'(\tilde{w}) \tag{14}$$

Properties 1 and 2 show that the firm responds in a natural way to the product price. Equation (14) shows a high product price ($\tilde{p} > \bar{p}$) will cause the firm to expand and the opposite for a low price. The difference between $\bar{p}$ the stationary equilibrium price and $\tilde{p}$ is shown to be directly related to the speed of adjustment of the firm, a property of adjustment paths that is often simply assumed. A property of more general price paths that will be useful for showing industry equilibrium is:

PROPERTY 3. (a) *If the price* $p(t)$ *is always above (below)* $\tilde{p}$ *then the optimal wage path* $w^*(t)$ *is always above (below)* $\tilde{w}$ *from (14).* (b) *If* $p(t)$ *converges from above (below) to* $\tilde{p}$ *where* $p_{min} < \tilde{p} < p_{max}$ *then the optimal path converges from above (below) to* $\tilde{w}$.

We have excluded the possibility of shutdown, but stated under what conditions it will occur, i.e., when the firm cannot avoid a loss. For a general price path (not necessarily constant), the shutdown could occur initially or, if price is decreasing over time, the firm might operate for a while and then shut down later. The possibility of layoffs, where some but not all workers are released, is more subtle. The only way this could occur would be if the firm were just indifferent between shutting down and continuing to operate, i.e., if the present value of the firm were zero when the optimal wage path was followed. Looking only at a single firm, it would seem a very remote possibility that price would just follow such a path. This is not so, as we shall see in the next section.

III. Industry Equilibrium

We now consider the industry which is made up of N firms like the one we have been discussing. The production function is assumed the same for all firms, and they all face the same product price and the same form of equations (4) and (9). This means that they will all set the same wage path and the same capital-labor ratio.[10] It is, of course, a simplifying device to consider a group of essentially identical firms, but it is a useful one. We can easily determine total industry supply and show that for any given demand function, the industry will converge to a stationary equilibrium. Total supply is given by:

---

[9] If the price remains above p_{max} for all time then the present value of the firm goes to infinity. See also the discussion of entry.

[10] One could allow for differences in efficiency or capital vintage across firms. This would complicate things considerably, however, because there would be a different wage for each firm. The industry output and price would depend upon the initial allocation of labor between firms.

$$
\begin{aligned}
(15)\quad X^s &= \sum_{1}^{N} F(K_i, L_i) \\
&= \sum L_i(\mathrm{t})f(k_i(\mathrm{t})) = \sum L_i(\mathrm{t})f(k(\mathrm{t})) \\
&= L(\mathrm{t})f(k(\mathrm{t})) \quad \text{where } L(\mathrm{t}) = \sum L_i(\mathrm{t})
\end{aligned}
$$

where L_i and K_i are now the employment and capital of the ith firm, L is the total industry employment, and $k(t)$ is the capital-labor ratio, common to all firms.

Industry demand is given by:

$$(16)\qquad X^d = Q(p(\mathrm{t})), \qquad Q' < 0$$

and it is assumed that there is always equilibrium in the product market so that:

$$(17)\qquad Q(p(\mathrm{t})) = L(\mathrm{t})f(k(\mathrm{t}))$$

Equations (1), (4), (9), and (17) will determine the path of price, wage, employment, and capital in the industry from any initial starting point $L(0)$. First, is there a stationary point for the industry? Second, will the industry converge to this point? If we constrain the demand curve by the condition

$$(18)\qquad Q(\bar{p}) > 0$$

where $\bar{p}$ is defined in Property 1, then continued production is profitable. There will then be a stationary solution for which $w = \bar{w}$ and $p = \bar{p}$, and in addition:

$$
\begin{aligned}
(19)\quad & k = \bar{k} \text{ from } \bar{p}f'(\bar{k}) = \rho \\
\text{and}\quad & L = \bar{L} \text{ from } Q(\bar{p}) = \bar{L}f(\bar{k})
\end{aligned}
$$

In general we would not expect the initial industry labor force to be just equal to the value $\bar{L}$ in (19). If $L(0) \neq \bar{L}$ we have the following:

THEOREM 1: *If all firms set the optimal wage path, then starting from any initial condition* $L(0) > 0$, *the paths of* $L(t)$, $p(t)$, $k(t)$, *and* $w(t)$ *will all converge to* $\bar{L}$, $\bar{p}$, $\bar{k}$, *and* $\bar{w}$.

PROOF:

Equations (4) and (17) can be solved for $p(\mathrm{t})$ and $k(\mathrm{t})$ in terms of $L(\mathrm{t})$: $L(\mathrm{t}) \lessgtr \bar{L} \Rightarrow p(\mathrm{t}) \gtrless \bar{p}$ and $k(\mathrm{t}) \gtrless \bar{k}$. If at any time τ, $L(\tau) = \bar{L}$, then $p(\tau) = \bar{p}$ and all firms would be following an optimal policy if they were to set $w(\mathrm{t}) = \bar{w}$ for all $\mathrm{t} \geq \tau$. This means that if the initial industry labor force is less than (greater than) the equilibrium value then it will never cross and become greater than (less than) the equilibrium level. Hence $L(0) \lessgtr \bar{L} \Rightarrow p(\mathrm{t}) \gtreqless \bar{p}$ for all $\mathrm{t} \geq 0$. We can therefore apply Property 3 to give:

$$(20)\qquad L(\mathrm{t}) \gtreqless \bar{L} \Rightarrow w(\mathrm{t}) \lesseqgtr \bar{w}$$

A simple Lyapunov function $V = 1/2(L(\mathrm{t}) - \bar{L})^2$ gives $DV = (L(\mathrm{t}) - \bar{L})DL$ and this ensures $L(\mathrm{t})$ converges to $\bar{L}$. Equations (4) and (17) then imply $p(\mathrm{t})$ and $k(\mathrm{t})$ converge to $\bar{p}$ and $\bar{k}$, and Property 3 implies $w(\mathrm{t})$ converges to $\bar{w}$.

A similarity was shown earlier between static monopsony and the stationary equilibrium in this model in that the wage is below the value of the marginal product. We now consider whether or not this means there are pure profits that would attract new entrants to the industry. This model is not the same as the case of a single monopsonist, however. The ability to extract a quasi rent from each worker derives from the monopsony power held over existing workers. A new entrant does not have any workers, but would have to acquire them by paying a wage premium. In fact, the quasi rent is not a pure profit. It is a return to the investment made during the acquisition of a labor force.

We do require a more complete specification of the labor supply condition which, as it stands, is not applicable to an entering firm. While space does not permit a full formal analysis it is not hard to see what is necessary. We now assume that *a new firm must incur a start-up cost, which* *includes the hiring of an initial minimum labor force,* that is at least as great as the cost to an existing firm of an equal expansion in its labor force. This seems reasonable enough since the kind of informational lags and reluctance to change jobs that created the labor supply conditions to existing firms will apply at least as much to potential entrants. Once established a new firm can expand according to equation (1).

Consider, therefore, a firm in equilibrium. Take equation (10) and express it more instructively as $h(\bar{p})=\bar{p}\partial F/\partial L=\bar{w}+r\lambda(\bar{w})$ using equation (5). We have seen that λ is the shadow price of a worker, the cost to the firm of acquiring an extra worker and his value to the firm. The worker is acquired by a kind of investment, by paying a wage premium over time. Hence the above condition states that the marginal product is equal to the wage cost of the worker plus the interest cost $r\lambda$ of an asset of value λ. Therefore the firm is not earning a pure profit, but only a normal rate of return r on the value of its past investment in obtaining a labor force. Since the marginal product of capital is always set equal to the rental rate on capital, the two conditions imply that the firms are operating where price just covers average total cost. Total cost includes the interest cost of the investment in workers. The potential entrant, by assumption, must pay at least λ for each worker so it will see only a normal or less than normal rate of return and will not be encouraged to enter.

The above argument will hold, of course, even more if price is below $\bar{p}$. Such a fall in demand would impose a capital loss on existing firms as the value of their acquired stock of workers falls. That is why they start to disinvest or reduce their labor force. In fact there is some L_{max} such that if the initial labor force were greater than this, price would be so low that firms would have a negative present value for all wage paths above w_{min}. The value of a worker has dropped to zero and firms will start to lay off workers. The price will then rise until the point where losses can be avoided and firms will then stop laying off.[11] Beyond this point the shadow price (and hence value to the firm) of each worker is again positive.

If on the other hand there is an increase in demand, it is natural to think that at some point when price is high enough, entry would occur. The only consequence for the model of such entry is that prices above this point would not be observed since they would generate entry and lower the price again. If the start-up costs were very large we could observe prices up to the p_{max} from equation (13). If the costs are smaller then there will be an effective maximum p_{max} between $\bar{p}$ and the solution of (13). If we redefine p_{max} in this way, it gives an economic condition more symmetric with p_{min} than the arbitrary mathematical condition (13).[12] Within the range p_{min} to the new p_{max} we have the interior solution given above. Outside this range we have shutdown or entry.

IV. Product Demand and the Wage

The framework in which the industry has been assumed to operate is purely static. We now assume that the overall economy is growing. There is labor-augmenting technical progress at a rate δ and population growth at a rate n. Consider the following form for the labor supply function:

$$\text{(21)} \quad \frac{DL^s}{L^s} = g(w,\, t) = g(we^{-\delta t})$$

and $\quad g(\bar{w}) = n$

---

[11] The firms stop laying off workers. They are still reducing the size of their work forces.

[12] Depending upon a taste for detail one could distinguish a p_{max} that would stimulate entry if it were sustained (as in the next section), and a price that was higher, but expected to fall.

The point of reference of the labor supply function has been shifted from zero to n to take account of the effect of the overall growth of the labor force. In addition the function shifts over time because technical progress is raising wages throughout the economy. The firms experience the benefits of the technical progress in terms of increased productivity as well as the cost of rising wages elsewhere. The maximization problem *for each firm* (excluding layoffs) is therefore given by:

$$(22)\qquad \max_{w_i, K_i} \int_0^\infty e^{-rt}[pF(K_i, L_i e^{\delta t}) - w_i L_i - \rho K_i]dt$$

$$\text{subject to}\quad \frac{DL_i}{L_i} = g(w_i e^{-\delta t})$$

If we define $y_i(t) = w_i e^{-\delta t}$ and define $k_i = K_i / e^{\delta t} L_i$ then (22) becomes:

$$(23)\qquad \max_{y_i, k_i} \int_0^\infty e^{-rt} e^{\delta t}[pL_i f(k_i) - y_i L_i - \rho k_i L_i]dt$$

$$\text{subject to}\quad \frac{DL_i}{L_i} = g(y_i)$$

This problem is exactly the same as the original one except $r-\delta$ replaces r. The same stability and convergence properties will therefore apply, and all firms will set a common wage and capital-labor ratio.

Population growth and technical progress mean that the overall economy is growing. We will assume that the rate of growth in the economy is at a constant rate $\alpha = \delta + n$. The rising income level will affect the demand for the industry's product. If we let the income elasticity of demand for the product be a constant m, then we have:

$$(24)\qquad X^d = Q(p)Y^m = Q(p)[Y_0 e^{\alpha t}]^m = Q(p)e^{m\alpha t}$$

where Y_0 is absorbed into the function Q. Total industry supply is given by

$$(25)\qquad X^s = \sum_1^N L_i e^{\delta t} f(k) = Le^{\delta t} f(k)$$

So that putting these together gives:

$$(26)\qquad Q(p)e^{m\alpha t} = Le^{\delta t} f(k)$$

The stationary solution of the previous section is now transformed into a steady-state solution with the properties:

$$(27)\qquad \begin{aligned} (DL/L)^* &= m\alpha - \delta \\ &= m(\delta + n) - \delta \\ \overset{*}{w} &= \overset{*}{w}_0 e^{\delta t} \\ g(\overset{*}{w}_0) &= m(\delta + n) - \delta \\ \overset{*}{p}[f(\overset{*}{k}) - \overset{*}{k} f'(\overset{*}{k})] &= \overset{*}{w}_0 + \frac{r - m(\delta + n)}{g'(\overset{*}{w}_0)} \\ \overset{*}{p} f'(\overset{*}{k}) &= \rho \\ Q(\overset{*}{p}) &= \overset{*}{L}_0 f(\overset{*}{k}) \end{aligned}$$

Such a solution will exist and the firms will all be following their optimal policies provided: (i) $L_0 = L^*$, (ii) initial demand for the product is large enough that $Q(p^*) > 0$, and (iii) that $r > m(\delta + n)$ so that the transversality conditions are satisfied. If $L_0 \neq L_0^*$ then Property 3 ensures that the industry will converge to the steady-state path.

THEOREM 2: *Starting from any initial industry labor force* (L_0), *then if all firms set the optimal wage and output path, the product price* $p(t)$, *the industry labor force* $L(t)$, *the capital-effective labor ratio* $k(t)$, *and the wage* $w(t)$ *will all converge to their equilibrium values* p^*, $L_0^* e^{[m(\delta+n)-\delta]t}$, k^*, *and* w^* (*from* (27)).

PROOF.

The theorem can be shown by the same method as that of Theorem 1.

On the steady-state path there is a simple relation between the product demand and whether or not the industry is expanding, high wage or contracting, low wage. Specifically:

$$(28) \qquad w^* \gtreqless \bar{w}$$

and hence $(DL/L)^* \gtreqless n$ as $m \gtreqless 1$

This result can easily be seen from (27) where m is the income elasticity of demand for the product. In an expanding economy, therefore, an industry that is experiencing relatively increasing demand for its product as income rises ($m>1$) will be a high wage industry. The interaction between product demand and the wage is hence of quite a different kind in the context of a growing economy. Discussions of the structure of wages usually see high or low wages as a disequilibrium response to unanticipated shifts in demand. Indeed the earlier results of this model were quite consistent with this view. In the growing economy, however, *wage differentials will occur as a natural response to the changing structure of demand.* Of course if the initial labor force is not L_0^*, then there will be an adjustment with the wage above or below its steady-state value.

The changing structure of demand is only a part of the story. So far, technical progress played only a very minor role in the results because the increasing productivity of labor was balanced by the rising level of wages throughout the economy.

V. Technological Change, Demand, and the Wage

We keep most of the framework of the previous section with the following modifications. The rate of technical change experienced by firms in this industry is γ which may be different from the rate for the economy as a whole δ.[13] It is a sufficient condition for a steady state to exist if we assume a Cobb-Douglas production function and a constant price elasticity of demand. Industry demand is then:

$$(29) \qquad X^d = ap^{-b}Y^m = ap^{-b}e^{mat}$$

where a and b are positive constants and Y_0^m is absorbed into a. The industry supply is given by:

$$(30) \qquad X^s = [Le^{\gamma t}]k^{\beta}, \qquad k = K/Le^{\gamma t}, \qquad 0<\beta<1$$

The steady-state solution is characterized by:

$$\begin{aligned}(31) \quad Dp/p &= (1-\beta)(\delta-\gamma)\\ Dk/k &= (\delta-\gamma)\\ DL/L = \theta &= (\delta-\gamma)(1-b)(1-\beta)\\ &\quad + mn + (m-1)\delta\\ &= g(\hat{w}_0) \quad \text{and} \quad \hat{w} = \hat{w}_0 e^{\delta t}\end{aligned}$$

There is also a set of initial conditions and we must have $r>\theta+\delta$ to satisfy the transversality conditions. The rate of technical change relative to the rest of the economy $(\delta-\gamma)$ determines the direction of changes in the steady-state price and capital-labor ratio. A rapid rate of technical change $(\gamma>\delta)$ means that labor costs are falling and this would mean a falling price of this industry's product. Looking at the capital-labor ratio, one can recall that the value of the marginal product of capital is always equal to the rental rate—assumed constant. A falling price lowers the value of the marginal product which must be offset by adjusting the capital-labor ratio. The above arguments hold in reverse for slow technical change.

The conditions that lead to a high or low wage are obtained from the third part of (31):

$$(32) \quad \hat{w} \gtreqless \bar{w} \quad \text{as} \quad \alpha(m-1) + (\delta-\gamma)(1-b)(1-\beta) \gtreqless 0$$

The first term of this expression is the same as the previous section; $\alpha=n+\delta$ is the rate of growth of income in the economy. This enters because for any income elasticity of demand, a different rate of growth leads to more or less rapid changes in the structure of demand. The term is positive or negative as m is greater or less than unity just as before. The effect of technical change is interesting in part because it is ambiguous. *Whether or not industry-specific technical change helps or hurts workers, i.e., leads to a high or low wage, depends upon the price elasticity of demand for the product.*

---

[13] This industry is small relative to the economy so that its rate of technical progress has a very small effect on the rate for the economy.

Rapid technical progress means that any given output can be produced with less labor.[14] The firms can economize on labor and keep the wage down. On the other hand, rapid technical progress allows the price to fall and this increases the quantity demanded. This effect tends to make the industry expansionary and high wage. Which of these two forces predominates depends on how elastic demand is. If the fall in price is a strong stimulus to demand ($b>1$), then rapid technical change will imply a higher wage than would be true for $\gamma=\delta$. If demand is inelastic ($b<1$), then rapid technical change implies economizing on labor and a lower wage.

VI. The Structure of Wages

Bearing in mind that caution needs to be exercised in applying a simplified model to empirical relations, we can nevertheless use the results when studying the pattern of relative wages. The dynamic monopsony specification *provides a framework to help understand that part of the relative wage structure associated with different growth rates, demand conditions, and rates of technological change.* Static supply and demand models of the labor market have to rely on *ad hoc* specification in order to explain why fast growing firms or industries tend to be high wage payers. Such models also give little information on the nature of the time path of the wage.

There is a very large literature on wage differentials, much of which focuses on skill and education differences. There is also a considerable literature on wages and mobility,[15] which gives some support to the underlying assumption of this model. Various incentive effects including a high relative wage reduce the quit rate and encourage hirings. It is common to include a measure of profitability to explain wage differentials.[16] One rationale for this is that workers ask for higher wages when profits are high. While this may be true, there is also a clear prediction from this model that a high product price that will imply high profits, will also imply a high wage set by the firm as a profit-maximizing path. The differences between neoclassical and institutional approaches to wage setting can hopefully be more easily clarified and resolved by an explicit dynamic profit-maximizing analysis.[17]

While many of the results of empirical studies are consistent with the model of this paper, there is not, to my knowledge, any paper that tests directly the predicted relations between wage and demand. One possible example that seems to fit the predicted result is agriculture, at least for an extended period up to 1972. The income elasticity of demand is low; the rate of technical progress has been very high; the price elasticity is low. Thus there is an unambiguous result from (32) implying a low wage declining industry. The limitations of steady-state results are indicated by the change in conditions experienced by agriculture in 1973–74 with the sudden spurt in foreign demand. Nevertheless, there were clear trends over a number of years which apparently fit this model.

---

[14] Part 2 of equation (31) shows that the capital-labor ratio is falling when $\gamma>\delta$ so that the marginal product of labor is falling. Also price is falling when $\gamma>\delta$ so that the value of the marginal product is certainly falling. Hence for constant output, the firm would economize on labor.

[15] See, for example, OECD, Lloyd Ulman, John Burton and John Parker, and references given by these authors.

[16] See, for example, Stuart Schweitzer.

[17] Ulman gives a discussion of alternative approaches and references.

APPENDIX

In this Appendix proofs are given of Properties 1–3 of the optimal path stated in Section II.

PROPERTY 1. *There is a unique price $\bar{p}$ that is consistent with stationary w, L, and K on the optimal path.*

PROOF:

If L is stationary then $DL=0$ and $w=\bar{w}$ so that equation (9) becomes:

$$h[p(\mathrm{t})] = \bar{w} + r/g'(\bar{w}) \tag{A1}$$

Given that, as we saw earlier, h is a monotonic function of p, (A1) defines a unique solution $p(\mathrm{t})=\bar{p}$. If $p=\bar{p}$, $w=\bar{w}$, and k satisfies equation (4) then all the necessary conditions of the problem are satisfied. In addition, F and g are concave and the transversality conditions are satisfied. Hence if $p(\mathrm{t})=\bar{p}$ for all $\mathrm{t}\geq 0$, we have found an optimal solution. The proof of Property 2 will show it is *the* optimal solution.

PROPERTY 2. *For any constant price $\tilde{p}$ such that $p_{min}<\tilde{p}<p_{max}$ there is a unique optimal wage path. This path is to set a constant wage $\bar{w}(\tilde{p})$ where $\tilde{p}$ and $\bar{w}$ are related by:*

$$h(\tilde{p}) = \bar{w} + \frac{r - g(\bar{w})}{g'(\bar{w})} \tag{A2}$$

and such that $\tilde{p} \gtreqless \bar{p} \Rightarrow \tilde{w} \gtreqless \bar{w}$

PROOF:

The function h is monotonic increasing. Differentiation of the right-hand side of (A2) shows that it is monotonic increasing in $\bar{w}$ provided $r>g$. This means that for any $\tilde{p}$ in the interval there exists a $\bar{w}$ which satisfies all the necessary and sufficient conditions for a maximum of the profit integral. It only remains to eliminate other alternatives. To prove: any optimal path must always be arbitrarily close to $\bar{w}$. Let w^* be an optimal path and define $\delta(\mathrm{t})=|w^*(\mathrm{t})-\bar{w}|$. From the necessary condition (9) we can then show that there exists an ϵ such that $|Dw^*(\mathrm{t})|=\epsilon(\mathrm{t})$ and ϵ is not arbitrarily small unless δ is. This is fairly clear intuitively from (9) but formal proof comes from a Taylor expansion of terms around $\bar{w}$. In addition, ***the sign of** Dw **is the sign of** $w(\mathrm{t})-\bar{w}$.* These two together mean that *if there is some τ such that $w^*(\tau)$ is not arbitrarily close to $\bar{w}$* then the optimal path $w^*(\mathrm{t})$ will move away from $\bar{w}$ for all $\mathrm{t}\geq\tau$. The rate of change $Dw^*(\mathrm{t})$ will not be arbitrarily small and will never become so because w^* is moving away from $\bar{w}$ for all $\mathrm{t}\geq\tau$. Hence w^* will reach w_{min} or w_M in finite time. But this cannot be optimal. Shutdown is not optimal because positive profits can be made. If the optimal path reaches w_M, the necessary condition says it can never get below w_M. But any path always above w_M violates the transversality condition and cannot be optimal. This provides a contradiction of the statement that $\delta(\mathrm{t})$ was not arbitrarily small for all t. Since any other optimal path cannot have any "daylight" between it and $\bar{w}$, then clearly $\bar{w}$ must be the unique optimal path.

PROPERTY 3(a). *If the price $p(\mathrm{t})$ is always above (below) $\tilde{p}$ then the optimal wage path $w^*(\mathrm{t})$ is always above (below) $\bar{w}$.*

PROOF:

This property is a straightforward extension of Property 2. We saw that the sign of $Dw(\mathrm{t})$ is the sign of $w(\mathrm{t})-\bar{w}$ when $p(\mathrm{t})=\tilde{p}$. This meant that if $w^*(\mathrm{t})$ ever went below $\bar{w}$ it would diverge to w_{min} and would not be optimal. This must hold a fortiori if $p(\mathrm{t})\geq\tilde{p}$ for all t. Similarly if $p(\mathrm{t})\leq\tilde{p}$ for all t, then w^* cannot go above $\bar{w}$ without diverging and again this is not optimal.

PROPERTY 3(b). *If $p(\mathrm{t})$ converges from above (below) to $\tilde{p}$, then the optimal wage path $w^*(\mathrm{t})$ converges from above (below) to $\bar{w}$, where $\bar{w}$ and $\tilde{p}$ are related by* (14) *and $p_{min}<\tilde{p}<p_{max}$.*

PROOF:

Define $u(\mathrm{t})$ and $v(\mathrm{t})$ by:

$$u(\mathrm{t}) = h[p(\mathrm{t})] - h(\tilde{p}) \tag{A3}$$

$$v(\mathrm{t}) = w(\mathrm{t}) + \frac{r - g(w)}{g'(w)} - h(\tilde{p}) \tag{A4}$$

Notice that from (12) $w=\bar{w}=>v=0$. The necessary condition (9) can be written:

$$\text{(A5)} \quad u(t) - v(t) = [g''(w)/g'(w)^2]Dw$$

Case 1: $p(t) \leq \bar{p}$. We know that $u(t) \leq 0$, $u(t) \rightarrow 0$ and, from (14) and Property 3(a), $v(t) \leq 0$. If there is ever a time τ such that:

$$\text{(A6)} \qquad |v(\tau)| - |u(\tau)| = \delta(\tau) > 0$$

then (A4) and (A5) show that this will be true for all $t \geq \tau$, and so $w(t)$ will decrease for all $t \geq \tau$. Such a path will reach w_{min} and cannot be optimal. Hence on the optimal path $|v(t)| \leq |u(t)|$ for all t. But since $u(t) \rightarrow 0$ as $t \rightarrow \infty \Rightarrow v(t) \rightarrow 0$ and $w^*(t) \rightarrow \bar{w}$.

Case 2: $p(t) \geq \bar{p}$ is proved in a similar way. It is slightly more complicated since if $w > w_M$ then $|v(t)|$ can become less than $|u(t)|$. It is still true that once $w > w_M$, it cannot get back, however, and this is all that is needed.

Academic Achievement and Job Performance

By David A. Wise*

This paper examines the relation of measures of academic achievement and other personal characteristics to job productivity of college graduates working in a large corporation. It was motivated by a desire to study the effectiveness of resource use in institutions of higher education.

Numerous studies of returns to investment in human capital have demonstrated quite clearly that the more educated earn more than those with less education.[1] These studies, however, do not tell us why this is so. Edgar Friedenberg has posed the issue as follows:

> Do schools contribute to economic opportunity? It can certainly be demonstrated that the longer one stays in school, up to 20 years at least, the higher one's income is likely to be. But whether this is due to capacities actually developed through instruction, or the effect on character and personality of decades of submission to school routines, or merely the consequence of a complex, interlocking series of credentials which restrict opportunities to those who have satisfied the authorities at an earlier stage is not clear. All these processes are involved and are interrelated. But I have listed them, I think, in ascending order of their influence, though apologists for the educational system would prefer, I believe, that the order be reversed. [p. 98]

Entry into higher level jobs is often restricted to college graduates, and in many cases graduate or professional degrees are required. Persons are selected and certified in the higher educational system largely on the basis of measures of academic aptitude or performance; but the relation between these measures and job performance (or productivity) is not generally known. The assumption of economic efficiency, however, would imply the existence of a causal relationship and equity would require it. A requisite of equity, or fairness, its intended meaning, would presumably be that persons with the same productive potential in an occupational field have the same opportunity to enter it. Such a requirement would not be met if persons were selected for jobs on the basis of "nonproductive" traits. This gives rise to two questions: First, is there a relation between an individual's ranking as determined by measures used to select and certify within institutions of higher education and his performance on jobs outside the educational system? Second, if there is a relation, why is it observed?

It may be useful to relate these questions to the notion of credentialism. A credential required by an employer could be, for example, a degree, a minimum class rank or grade point average, graduation from a college of at least some minimum quality, or a combination of these. We would like to know whether or not a college degree represents more than simply a credential

---

* Assistant professor, Harvard University. This research was supported by the Ford Foundation Program for Research in University Administration. I have benefited from many discussions with Roy Radner, for whose advice and suggestions I am especially grateful. I would also like to thank Lloyd Ulman, Paul Taubman, George Borts, and an anonymous referee for their very helpful comments. Responsibility for remaining shortcomings, of course, remains with me. In addition, I acknowledge the generous and invaluable assistance of Paul Banas, Personnel Research Section, Fort Motor Company, in obtaining the data used in the study.

[1] See, for example, Gary Becker, Giora Hanoch, Lester Thurow (1967).

requirement. Is it also an indicator of productive ability? If it is, then we might expect degrees of "different quality," as measured by differences in academic achievement, to indicate different levels of productive ability. If the degree is an indicator of productive ability, we would like to know, in addition, whether or not a college education contributes to one's productive ability. This is the essence of the second question.

I. Background and Outline

A. *The Initial Question*

Selection in the higher educational system is currently based primarily on measures of cognitive abilities[2]—grades,[3] achievement tests, and aptitude tests.[4] In short, students tend to be selected on the basis of their promise as future students in the existing educational structure. Certification involves primarily the assigning of grades (presumably to indicate the degree of mastery of academic subject matter) and the awarding of degrees along with verification that a certain amount of time has been spent in school and specific courses.

Several authors have concluded, however, that these measures are not correlated with job performance in many occupations, even though they may be used in occupational selection.[5] The initial and primary focus of this paper is an examination of this conclusion when applied to a sample of individuals who work in a large corporation, not unlike many others. The absence of a significant relation between academic achievement and job performance may be taken as a null hypothesis. This hypothesis is rejected in this case, and we are led to ask why.

B. *The Second Question*

According to human capital theory,[6] an individual chooses the occupation and level of education that maximize the present value of his expected lifetime earnings. It is generally assumed that education changes an individual in such a way as to increase his capacity to perform job-related tasks. Although not necessary to the theory, it is also implicitly assumed that the knowledge and other cognitive skills gained in school increase his productive capacity.[7] But it may be that this is not the primary reason for observed differences in earnings by educational level. The educational system may select persons who are more productive, but not increase their productive potential; it may serve simply as a screening device. Recent theoretical examples of this have been presented by Michael Spence and Kenneth Arrow. And if education does increase productive potential, it may be by way of changes in affective rather than cognitive attributes. This possibility is not inconsistent with human capital theory, but may suggest changes in emphasis within the educational system.

---

[2] The terms "cognitive," "affective," "academic," and "nonacademic" are used rather loosely throughout the paper. Cognitive and affective are used to distinguish personal traits which Benjamin Bloom describes in terms of educational objectives as follows:

> The cognitive domain . . . includes the objectives which deal with the recall or recognition of knowledge and the development of intellectual abilities and skills. . . .
>
> The affective domain . . . includes objectives which describe changes in interest, attitudes, and values, and the development of appreciations and adequate adjustment. [p. 7]

The terms academic and nonacademic are often used in referring to cognitive and affective traits, respectively. The distinctions are quite imprecise and should be interpreted accordingly.

[3] Grades may not measure only cognitive abilities. See Herbert Gintis, for example.

[4] See *The Student in Higher Education*. See also the *Report of the Commission on Tests* of the *CEEB*, Leonard Baird and John Holland, and Baird and James Richards.

[5] In his study relating primarily (but not exclusively) to blue collar workers, Ivar Berg claims that there is little or no relation between job performance and education. Another investigator, Donald Hoyt, reviewed 46 studies relating college grades and adult achievement in several areas and in the summary stated ". . . present evidence strongly suggests that college grades bear little or no relationship to any measures of adult accomplishment." Similar conclusions have been suggested by others. See, for example: Seth Payne, who remarks on studies by the National Advisory Committee for Aeronautics (now part of *NASA*) and Hughes Aircraft Company; Calvin Taylor and Robert Ellison; Donald MacKinnon; D. A. Goslin (1963, 1968); Dael Wolfle.

[6] See Becker or Thurow (1970). The conventional theory is summarized by Yoram Weiss in a more recent article.

[7] In fact it may be explicitly stated. Becker, for example, states: "On-the-job and school training are not the only activities that raise real income primarily by increasing the knowledge at a person's command" (p. 31). See also p. 86 of the same source.

The screening hypothesis suggests the possibility that higher earnings of the more educated result in part from credential requirements which restrict entry to many occupations on the basis of educational level. Even in an extreme case in which (college) education does not change the productive capacity of students in any way, a positive relation between earnings and education might be observed. In general, what is required is that the cost of education to an individual be a decreasing function—or that the availability be an increasing function—of productive traits, that employers set wages to maximize expected profits, and that individuals choose an educational level to maximize expected earnings.[8]

Several investigators[9] have attempted to control for intelligence in studies relating earnings to education. In general, these studies suggest a rather low contribution of intelligence (as measured) to earnings when level of education is controlled for.[10] This may, however, be due in part to occupational entry requirements based on level of education and limits on potential earnings within occupations. In addition, earnings may not be highly related to performance in occupations in which earnings are largely determined by established wage scales and promotions are based on seniority.

Gintis has argued that noncognitive traits which lead to academic achievement are also required for success in bureaucratic organizations. He contends that it is these affective traits fostered by the educational experience (or at least rewarded by the educational system), and not cognitive development, which are largely responsible for the increased earning power of the more educated. His argument also neglects credential requirements, which may limit the explanatory power of cognitive ability when educational level is controlled for.

After examination of the relation of measures of academic achievement and other personal characteristics to job productivity in Section II, subsequent discussion in Section III will explore implications of the findings with respect to these questions.

C. *The Data*

This investigation is based on the performance of individuals with a given level of education, but different levels of academic achievement, who work in a particular environment and perform similar tasks. The data pertain to individuals working in a large manufacturing corporation employing both technical and nontechnical personnel. The sample included persons employed in all parts of the country, although a large proportion were employed in a single region. In 1968 the corporation obtained biographical information and data on salary and position in the corporation of approximately 1300 college graduates employed at that time. All were hired before 1965, and all were not more than 30 years old when they were hired. Thus, most had little or no previous job experience. Those surveyed represented a stratified random sample (by function—manufacturing, finance, sales, etc.—and hierarchical position in the firm) of approximately 6800 persons who met these requirements. All persons in the sample were white males. Biographical information pertained to socioeconomic background, high school and college nonacademic activities, academic performance (grades), college attended, employment goals, early employment experiences with the firm, and other personal characteristics. Data on salary, position in the firm, years employed, and college attended were obtained from personnel records; all other information was obtained by survey. Excluded from the sample were: persons hired before 1945, because the relation between salary and years employed differed markedly between this group and the group hired later; and persons who had an M.A. degree when they joined the firm.

---

[8] Spence presents several examples in which the cost of education is related to a productive trait. Similar examples are presented by Arrow.

[9] See, for example, Zvi Griliches and William Mason, Otis Duncan, Carl Bajema, Orley Ashenfelter and Joseph Mooney, and Lee Hansen, Burton Weisbrod, and William Scanlon.

[10] The study by Hansen, Weisbrod, and Scanlon is an exception, as is the more recent work of Paul Taubman and Terence Wales.

D. *The Measurement of Job Performance*

There seems to be no completely satisfactory way of measuring job performance, or even of defining it. We therefore resort to the assumption that differences in individual job performance are reflected in measures of success within the firm; that rewards within the firm are based on job performance, or at least on perceived performance. In this case, there are two available measures of success: salary and grade level. The model of individual experience within the firm proposed below is intended to be consistent with salary as a measure of success. If in fact, as is commonly assumed, an individual's lifetime earnings reflect his marginal product, the link between salary and job performance is rather direct. However, the relation between individual attributes and reward by the firm is of interest whether or not earnings reflect marginal product.[11]

E. *Summary of Results*

The relation between college quality and grades on the one hand and this measure of job performance on the other is not only statistically significant but is quantitatively important. Thus, it would appear that criteria used for selection and certification are positively associated with an individual's ability to perform job-related tasks. The findings of the study suggest that this relation is not simply due to noncognitive attributes such as motivation or to "innate ability" such as IQ, which may underlie academic success; but that academic achievement is an important determinant of job performance. The existence of such a relationship is not, however, directly demonstrated here; only indirect evidence is provided. A direct measure of IQ, for example, is not available.

The results also suggest that nonacademic attributes are as important as academic abilities in determining job performance. Leadership ability and initiative (or job experiences that allow imaginative thinking or expression of one's ideas) are found to be positively associated with job performance, while a negative relation is observed between an individual's desire for job security and his job success. An important characteristic of the sample data was the low correlation between academic and nonacademic variables, so that identification of separate effects of these variables was not hampered.

---

[11] Another model, which is used with grade level as a measure of success, has been suggested elsewhere by the author (1972, 1975), but is not discussed in detail here. It is based on the assumption that persons move through grade levels within the firm or leave the firm according to a Markov scheme and that relative job performance is reflected in the probability of promotion from one grade level to the next.

II. Salary and Personal Attributes

A. *The Variables*

Job productivity is assumed to be influenced by a variety of cognitive and affective traits, none of which is measured precisely by available data. Those variables assumed to reflect primarily academic aptitude or achievement are high school grade point average, college selectivity, college grade point average, and rank in graduate class for persons who obtained an M.A. degree after joining the firm. The variables assumed to measure nonacademic attributes are indices that were obtained by combining responses to groups of biographical questions. The indices are referred to as: socioeconomic index, leadership and organizational ability index, initial experience (or initiative index), initial supervisor experience, and job security index. Each index represents the first principal component relative to responses to a group of questions. For convenience, each index has been scaled to have mean zero. This procedure and the rationale for its use have been discussed by the author in some detail elsewhere.

It is assumed that socioeconomic background affects not only the quality of education an individual obtains, but it may also have some independent effect on nonacademic traits which influence later job performance in a corporate (or bureaucratic) environment.[12] The leadership and organization ability index is assumed to characterize, in part, an individual's past demonstrated ability as a leader or organizer.

The initial experience index may be interpreted in two ways. It may indicate the existence of a particular environment during an individual's first years with the firm. But it may be more likely to reflect an individual's personal behavior; in this case traits such as initiative, decision-making ability, or imaginative thinking. The initial supervisor index seems to be less indicative of the respondent's behavior and more representative of his initial work environment—the extent to which his initial supervisor included him in the decision-making process and pushed for his advancement.

The job security index (based on the response to only one question) may be interpreted in two ways. First, as a measure of risk aversion. The higher a person progresses in the firm hierarchy, the greater is the likelihood that he will have to make decisions, the consequences of which are traceable to him.[13] A second possibility is that the response simply reflects an individual's confidence or "self-assurance" (see Ghiselli). Persons who are not worried about job security may feel confident that they can make the right decisions.

The correlations between academic and nonacademic variables (excluding the socioeconomic index) are quite small in most cases.[14] The two groups of variables seem to reflect largely independent individual (or job environment) attributes.

---

[12] See, for example, Edwin Ghiselli who emphasizes the importance of "perceived occupational level" as a determinant of managerial success. This might be influenced by the socioeconomic background of one's parents. See also Edwin Robinson, Robert Athanasiou, and Kendra Head, and M. Winterbottom.

[13] In this regard, a firm employee stated that at particular grade levels, persons tend to come under "scrutiny" by higher management.

[14] The correlations are not shown here, but interested readers may obtain them from the author. The low correlations between academic and nonacademic variables are consistent with the findings of other investigators. See, for example, Jacob Getzells and Philip Jackson and MacKinnon, who find weak relations between intelligence and creativity; Holland and Richards (1965, 1966), and Holland and R. Nichols, who find that academic and nonacademic (extracurricular) achievement in high school and college are "relatively" independent. Similar evidence is provided by Baird and Holland, and J. Flanagan et al.

B. *The Model*

In what follows it is implicitly assumed that differences among individuals in expected lifetime earnings reflect differences in the performance of tasks considered important to the functioning of the firm. Those who "do better" are rewarded with higher incomes. A more conventional assumption would be that the marginal product of a person who stays in the firm is given by his expected lifetime earnings. The results below, however, are in no way dependent on an individual being paid the value of his marginal product.

Let us assume that the monthly salary of a person who has been employed by the firm for t years is given by

$$s = e^a e^{rt} e^{\epsilon} \tag{1}$$

where e^a represents starting salary, r is the rate of increase in monthly salary, and ϵ is a disturbance term. (As indicated below, this functional form is used because it is more consistent with the experience of persons in the sample than are other alternatives.) Both a and r are assumed to be functions of personal characteristics:

$$a = g_0(x) \tag{2}$$

$$r = g_1(x) \tag{3}$$

where x is a vector of individual (and possibly job environment) attributes. Not all elements of x will enter both g_0 and g_1 with nonzero coefficients.

The estimated model allows starting salary and rate of salary increase to vary with personal characteristics according to particular functional forms (see (5) and (6) below). Taking the logarithm of (1) and substituting these functional forms, we obtain the estimated model (7) as follows:

$$ln\ s = a + rt + \epsilon \tag{4}$$

$$a = g_0(x) = a_0 + a_i + b_j + dx_0 \tag{5}$$

$$r = g_1(x) = r_0 + \alpha_i + \beta_j + \gamma_k + \Sigma_{l=1}^{5} \delta_l x_l \tag{6}$$

where the following identifying restrictions are imposed.

$$\Sigma_i a_i = 0, \qquad \Sigma_j b_j = 0, \qquad \Sigma_i \alpha_i = 0,$$
$$\Sigma_j \beta_j = 0, \qquad \Sigma_k \gamma_k = 0$$

Then,

$$ln\ s = a_0 + a_i + b_j + dx_0 + [r_0 + \alpha_i + \beta_j + \gamma_k + \Sigma_{l=1}^{5} \delta_l x_l]\text{t} + \epsilon \tag{7}$$

The analysis of covariance formulation depicted in (7) was estimated by ordinary least squares.

As above, s represents monthly salary and t, years employed; d and δ are coefficients. The other symbols are defined in the list below. All but x are parameters to be estimated. The mnemonic abbreviations to the left of the symbols are used throughout in tables and tabulations.

Constant $= a_0 \equiv$ constant
BA $= a_1 \equiv$ effect of having B.A. degree when start work at the firm
BA' $= a_2 \equiv$ effect of not having B.A. degree when start work at the firm
ENG $= b_1 \equiv$ effect of engineering or science undergraduate major
LIB $= b_2 \equiv$ effect of liberal arts (or other) undergraduate major
BUS $= b_3 \equiv$ effect of business undergraduate major
EXP $= x_0 \equiv$ years of experience (excluding military) before coming to the firm
AV $= r_0 \equiv$ "average" rate of salary increase
SEL(i) $= \alpha_i \equiv$ effect of undergraduate college in *i*th selectivity group

$GPA(j) = \beta_j \equiv$ effect of undergraduate grades in jth interval

$MA(k) = \gamma_k \equiv$ effect of being in kth rank in M.A. class (γ_0 is for B.A. only)

$SEC = x_1 \equiv$ index of desire for job security

$SES = x_2 \equiv$ socioeconomic background index

$LEAD = x_3 \equiv$ leadership and organizational ability index

$INT = x_4 \equiv$ initial job experience index

$SUP = x_5 \equiv$ initial supervisor index

A few persons joined the firm before they received a bachelor's degree; they are distinguished from those who had a degree when hired. Information on job experience before joining the firm was not available. The previous experience variable is a crude estimate made from available information. Colleges were assigned to groups on the basis of Alexander Astin's (1965b) college selectivity (*SEL*) index.[15] This index is intended as a "measure of the average ability level of the entering class." The grade point average (*GPA*) intervals are those designated in the firm survey.[16] Rank in graduate school pertains to those who obtained a master's degree after joining the firm. Those in group 1 graduated in the top 5 percent of their graduate class; group 2, in the top one-third; and group 3, in the lower two-thirds. The final group, indexed by 0, represents those with a B.A. degree only. The last five variables, which have been discussed earlier, are treated as continuous.

It may be noted that the model as stated does not allow selectivity or college grades to enter into the determination of starting salary; they only affect the rate of salary increase. This is not an arbitrary assumption but is based on previous analysis of the data (see my earlier paper). Appropriate formulations of the model indicated that starting salary was not appreciably affected by college selectivity or grade point average, contrary to a priori expectations. Firm employees confirmed that, in the interest of morale, these variables were not normally considered in determining starting salary. Of course, it could be that the firm did not believe that differences in college selectivity and grade point average among persons hired represented significant differences in productive ability. Models allowing prior military service to influence starting salary and undergraduate area of study to affect the rate of salary increase were also tried. These factors seemed unimportant and were eliminated from later analysis.

In addition, the model as stated does not allow for interactions between college selectivity and college grades (or between rank in graduate school and either of these). This was not feasible with six selectivity groups and four grade point average groups; but the significance of interactions was tested for in a model with only three groups for each. Interactions were shown not to be statistically significant in this case, and it has been implicitly assumed that they would not be significant if they were included in the model with more groups.

Finally, the model assumes a constant rate of salary increase over an individual's working lifetime. It is normally assumed that the rate of increase decreases and may become negative at some point. The data used here did not exhibit this characteristic, although a model with salary, rather than the logarithm of salary, expressed as a linear function of years employed yields results comparable to those obtained with the above model. It should be remembered that the available data pertain to persons employed no longer than twenty-two years.

---

[15] The groups and corresponding intervals are as follows: *SEL1*, 73–79; *SEL2*, 66–72; *SEL3*, 61–65; *SEL4*, 56–60; *SEL5*, 47–55; *SEL6*, 37–46.

[16] The groups and corresponding intervals are: *GPA1*, 3.50–4.00; *GPA2*, 3.00–3.49; *GPA3* 2.50–2.99; *GPA4* less than 2.50. *GPA4* combines the lowest two intervals as designated in the survey.

It should also be kept in mind that data are available on salary only, which may comprise only a portion of total income from the firm. As one rises in the firm hierarchy, bonuses and stock options are likely to comprise an increasingly large portion of total income and may even be more important than salary at very high levels.[17]

C. *Results*

Estimates of the parameters in equation (7) obtained by ordinary least squares[18] are shown in Table 1. The F-statistics pertain to the null hypothesis that the parameters indicated are all zero, which in the case of the discontinuous variables is equivalent to the hypothesis that the effects are the same for all groups (for example, all college selectivity groups). In each case, the hypothesis is rejected at any reasonable level of significance.[19] Estimates given in the upper portion of the table relate to determinants of starting salary a, and those below to the rate of increase in salary r.

The estimates regarding starting salary confirm what might be expected. Persons with a bachelor's degree had a higher initial salary than those who started work before obtaining a degree. The estimates also indicate that persons whose undergraduate major was engineering or a science commanded higher initial salaries than those who majored in liberal arts or business. A comparison of the previous experience coefficient with the average rate of salary increase indicates the relative value the firm places on experience prior to joining the firm versus experience in the firm.[20]

[a] The standard error for the estimate of the effect of being in the lowest interval of a variable (e.g., *SEL6*) is not shown because the computer program used did not compute a variance-covariance matrix.

---

[17] A plausible functional relation between total earnings (E) and salary (s) is $E=s^k$, where k is some constant greater than one. In this case, the use of total earnings instead of salary would not qualitatively affect the estimates of the parameters, a and r in (1). They would simply be increased by a factor of k. Differences in total lifetime earnings among individuals would, of course, be much larger than differences in lifetime earnings from salary.

[18] One would expect heteroscedasticity in a regression of salary on the right-hand variables included here. Using $\ln s$ instead of s tends to reduce the problem, but does not eliminate it, judging from a plot of residuals against years employed. Attempts to correct for this, however, did not appreciably alter the parameter estimates or their standard errors.

[19] $F_{.01}(5, 976)=3.02$, $F_{.005}(5, 976)=3.35$.

[20] According to these estimates, the average person with x years of experience outside the firm would receive an initial salary of $ke^{.016x}$ (where k is a constant)

(over)

TABLE 2—ESTIMATED RATES OF SALARY INCREASE FOR PERSONS WITH A B.A. DEGREE BY COLLEGE SELECTIVITY-COLLEGE GRADE-POINT AVERAGE GROUP

Without *SEL-GPA* Interactions[a]

	SEL1	*SEL2*	*SEL3*	*SEL4*	*SEL5*	*SEL6*
GPA1	.05643	.04792	.04680	.04375	.04127	.03731
GPA2	.04921	.04070	.03958	.03653	.03405	.03009

GPA4	.04279	.03428	.03316	.03011	.02763	.02367

With *SEL-GPA* Interactions[b]

	SEL1-2	*SEL3-4*	*SEL5-6*
GPA1-2	.04395	.03806	.03442
GPA3	.03794	.03423	.02923
GPA4	.03448	.03078	.02607

[a] Calculated from estimates in Table 1, $[AV+MA_0+SEL(i)+GPA(j)]$.

[b] Calculated from a regression equation allowing for *SEL-GPA* interactions.

The "average" rate of increase in salary is estimated to be .045. The estimated rate of salary increase goes up consistently with college selectivity, college grades, and rank in graduate class (if a higher degree is obtained). The relationships, however, are seen to be non-linear.[21]

The effect of graduate education after joining the firm can be seen by combining the average rate of increase with the effects for rank in graduate school. The average rates of increase by rank in graduate class are as follows:

Rank in Graduate Class	Estimated Rate of Salary Increase
Top 5 percent	.057
Top ⅓, excluding top 5 percent	.045
Bottom ⅔	.040
B.A. only	.038

According to these estimates, obtaining a master's degree has almost no effect on an individual's rate of salary increase, unless he graduates at least in the top third of his class. Simply obtaining a certificate has no appreciable effect.

From the parameter estimates in Table 1, the implied rates of salary increase by selectivity and grade point average group for persons with a bachelor's degree only have been calculated. They are shown in the first half of Table 2. The estimate in the *i*th column and the *j*th row is obtained as follows: $AV+MA_0+SEL(i)+GPA(j)$. The estimated rate for persons from the highest selectivity schools and with the highest grades is more than twice as high as the rate of increase for persons from the lowest selectivity schools and with the lowest grades. These are not independent estimates. For comparison, independent estimates for fewer categories calculated from parameter estimates from a regression with selectivity and grade point average interactions are shown in the second half of Table 2.

The estimates of the parameters corresponding to the nonacademic variables are all significant except the coefficient on socioeconomic background. Apparently,

---

while a similar person with z years of experience within the firm and no previous experience would be earning an amount $ke^{.045z}$. Although the coefficient on *EXP* may be underestimated, it might be expected to be quite low, because the previous experience for many people in the sample may have been in work unrelated to that of the firm. In addition, part or all of the estimated previous "experience" for an individual could have been time spent without a job (after college) or time spent looking for work. In any case, the estimated coefficient should be interpreted cautiously.

[21] The apparent nonlinearity in selectivity may result in part from the way in which the index was standardized (see Astin (1965b)).

its influence is only by way of its effect on academic achievement. The coefficient is significant when college selectivity is left out of the equation.

One way to evaluate the relative influence of the continuous variables is to compare changes in the rate of salary increase Δr, resulting from standard deviation increases. These changes are shown in the following tabulation.

Variable	Sample Standard Deviation	Δr
SEC	1.130	−.00350
SES	1.452	.00044
LEAD	1.557	.00339
INT	2.113	.00148
SUP	.1487	.00211

The change due to a standard deviation increase in the job security or leadership index is approximately the same as the increase resulting from a shift from the fourth to the third, or from the third to the second, college grade groups. The effects of the initial experience (or initiative) and initial supervisor indices are considerably weaker. The latter variables presumably pertain only to an individual's initial experience in the firm, whose effects may tend to disappear as the number of years employed increases.[22]

An idea of the relative contribution of academic versus nonacademic variables in the "determination" of salary may be obtained by comparing values of R^2 obtained when different groups of variables are included in the regression. Selected groups of variables and corresponding R^2 values are as follows.

Right-Hand Variables Included	R^2
1) All Variables	.690
2) t (years employed) only	.490
3) t, plus variables affecting starting salary: *BA*, *ENG*, *LIB*, *EXP*	.530
4) t, *BA*, *ENG*, *LIB*, *EXP*, plus academic variables: *SEL*(*i*), *GPA*(*j*), *MA*(*k*)	.622
5) t, *BA*, *ENG*, *LIB*, *EXP*, plus nonacademic variables: *SEC*, *SES*, *LEAD*, *INT*, *SUP*	.633

The percentage of the variation remaining unexplained after variables 3) are included, which is explained by the academic and nonacademic variables together, is .340. $[(.690-.530)\div(1-.530)=.340]$. A high estimate of the contribution of academic variables is the proportion of remaining variance explained when they are added to the regression in the absence of nonacademic variables; a low estimate is the addition to the proportion explained when they are added after the nonacademic variables.[23] In this case, the high and low estimates are $[(4)-(3)]/[1-(3)]$ and $[(1)-(5)]/[1-(3)]$, respectively. The opposite is true for the nonacademic variables. This yields the following results: academic variables—low, .121; high, .196 and nonacademic variables—low, .145; high, .219.

D. *Undergraduate versus Graduate School Achievement*

Further insight into the relation between salary progress and graduate education may be gained by considering the mean of a salary index (described in the note to Table 3) by undergraduate grade point average (*GPA*) and rank in graduate school (*MA*). These figures are presented in Table 3.[24] They confirm the findings

---

[22] The appropriate interpretation of these variables is also less clear than that of *LEAD* or *SEC*. If, for example, *INT* is assumed to measure initiative, it may do so with considerable error, thus tending to "bias" the estimated coefficient toward zero. In other words, the extent of the error in variables with respect to *INT* and *SUP* is likely to be larger than for *SEC* and *LEAD*.

[23] The two estimates would be the same, of course, if the two groups of variables were orthogonal. In this case, the most highly correlated variables are *SES* and *SEL* (−.22), *SEC* and *SEL* (.20), and *SUP* and *MA* (*k*) (.23).

[24] Other variables have not been controlled in making these estimates. It might be assumed, for example, that

TABLE 3—MEAN OF SALARY INDEX BY UNDERGRADUATE MAJOR AND *GPA-MA* GROUP FOR PERSONS WHO OBTAINED AN M.A. DEGREE[a]

	Total Sample		Engineering or Science		Business	
	MA1–2	*MA3*	*MA1–2*	*MA3*	*MA1–2*	*MA3*
GPA1–2	23.26 (4.12) $n=39$	10.85 (4.12) $n=15$	34.97 (7.75) $n=13$	18.78 (10.55) $n=7$	16.04 (4.90) $n=21$	2.23 (10.04) $n=5$
GPA3–4	11.90 (4.29) $n=36$	3.44 (4.48) $n=33$	20.91 (7.21) $n=15$	0.50 (7.21) $n=15$	5.29 (5.61) $n=16$	1.91 (6.23) $n=13$
Total:		13.10 (2.39) $n=123$		18.14 (4.25) $n=50$		8.31 (3.06) $n=55$
R^2		.084 $F(3, 119)=3.65^*$		.190 $F(3, 46)=3.62^*$		.076 $F(3, 51)=1.40$

Model: $e_{ijk}=\beta_{ij}+\epsilon_{ijk}$, where e_{ijk} is the index number for the kth person in the ijth *GPA-MA* group and β_{ij} is the mean of the index numbers for persons in the ijth *GPA-MA* group.

[a] The index is the residual from a regression of salary on years employed where a correction has been made for heteroscedasticity. The total sample was used in this regression. The index would of course have mean zero over all individuals in the sample. As can be seen, M.A. holders have salary index numbers greater than zero on the average in all *MA-GPA* groups. Figures for liberal arts majors are not shown because of the small number of observations in each cell. Numbers in parentheses are standard errors of estimates. (They are to be interpreted the same as standard errors in any regression model; in this case β_{ij} are parameters estimated.) For example, the mean of the salary index for engineers in group *GPA1–2/MA1–2* is 34.97. The standard error of this estimate is 7.75. The F-statistic relative to the hypothesis that the means of all four engineering groups are the same is 3.62. A * indicates that the hypothesis is rejected at the .05 level of significance. The number of observations in the group is n.

presented in Table 1, but suggest a considerably larger effect of the master's degree on earnings for engineers or scientists than for students of business administration. In this case, one might expect a stronger effect for engineers because of the relatively unique combination of technical and managerial skills which they might be expected to possess.

III. Further Implications

The above analysis has been directed primarily toward the following question. What is the relation, if any, between academic achievement and other nonacademic attributes of college graduates and job performance (or productivity) outside the educational system? A consistent positive relation between commonly used measures of academic achievement and rates of salary increase has been found. Of those attributes of individuals that have been controlled for, academic and nonacademic characteristics seem to be of approximately equal importance in explaining differences in salary. Both, however, explain a relatively small proportion

---

persons with better undergraduate records were able to get into better graduate schools and that the difference in salary by undergraduate *GPA* is partially the result of this effect. Since, however, these persons obtained an M.A. at the same time that they were working, it is likely that the best graduate schools were not represented in the sample, and that the difference in the quality of those represented was not large.

of the total variation in salary. This is not surprising, since the individuals all had the same quantity of education when they started work and all were presumably selected with the expectation that they would be able to perform at least adequately. (If persons with poor academic credentials were hired because they were strong on other attributes not controlled for, the observed effect of academic characteristics would tend to be biased downward.) The Markov model explored elsewhere by the author (1972, 1975) explicitly implies a limit on the explanatory power of individual attributes.

Observed differences in salary are of course affected by on-the-job training, as well as academic training and other personal attributes. (See Jacob Mincer, for example.) This type of learning has not been accounted for here.

In addition to the above findings, the results may also provide some insight into the more difficult and more fundamental questions that were posed at the beginning of the paper. The implications with respect to these questions are less clear than the implied relation between academic achievement and job productivity. They essentially ask why this relation is observed.

A. *Intelligence or Academic Aptitude*

Let us consider first the possibility that success in mastering academic subject matter is not a determinant of job performance. Rather the observed relation between college grades and salary results from the fact that persons who got good grades had higher innate intelligence or academic aptitude than those who did not.[25]

We do not have a good control for academic aptitude. However, the variation in academic aptitude (Scholastic Aptitude Test (*SAT*) scores) among students in a college decreases with it's selectivity. There is little variation in the most selective schools where all students have high aptitudes. But even among persons from the best schools we observe a consistent effect of college grades. Looking at the second half of Table 2 we observe that the effect of grades on the rate of salary increase seems not to depend on selectivity. The difference between the estimated effects of the highest and lowest college grade groups is .0095 in the highest selectivity group and .0084 in the lowest. (The numbers represent differences in rates of salary increase.) If grades were serving only as a proxy for aptitude, one might expect the observed effect of grades to decrease with college selectivity.[26] "Lifetime earnings" not only increase with the rate of increase in salary, but do so at an increasing rate.[27] The higher the selectivity group, the higher the rate of increase in salary for any grade point average level. It could be that differences in grades represent relatively larger differences in knowledge in better schools. It is also possible that "smarter" persons can make better use of knowledge on the job.

---

[25] It is, of course, unreasonable to think that intelligence alone determines job performance. Most jobs require mastery of certain skills such as reading and writing. But we are here considering the effects of college education, and are referring to intelligence given that a person obtained a high school degree. Even in this case, some skills (e.g., techniques for engineers) may be necessary; but the mastery of these skills above some minimal level may not be relevant.

[26] Average *SAT* scores at the best schools are very high and there is very little variation among the scores. See, for example, Astin (1971). It should also be noted, however, that differences in the variation of *SAT* scores may not be an accurate representation of differences in the variation of underlying aptitude. This may be especially true at better schools where many persons score at the top of the *SAT* scale. In addition, these scores represent an ordinal ranking and not a cardinal measure.

[27] This is a property of the functional form used, and should not be overemphasized. To demonstrate it, let T be the number of years a person works (we are limited by the data to 22 years), k be starting salary, and let LE represent expected lifetime earnings (i.e., the integral from 0 to T of ke^{rt}). It may be seen that the second derivative of lifetime earnings with respect to r must be greater than zero.

It has been implicitly assumed that the observed relation between rate of salary increase and college selectivity is primarily due to the higher average scholastic aptitude of persons from better schools. It is also possible that persons from better schools learn more than those in poorer schools, so their accrued academic knowledge is greater.

B. *Affective Traits*

It has been suggested that observed differences in job performance by grade point level may be due to nonacademic traits which are possessed to a greater extent by persons who do well in school than by those who do poorly (see Gintis, for example). An attempt has been made to control for some of these traits in the estimation procedure by incorporating the indices for security, leadership, socioeconomic background, and initiative—certainly an incomplete representation. However, it seems reasonable that job productive traits not controlled for, which also influence performance in college, would affect high school performance.[18] If college grades are serving only as a proxy for excluded affective traits, high school grades may be a reasonable proxy as well. Then if high school grade point average were introduced into the regression equation, the effects of college and high school grades should be confounded, at least to some degree. When this is done, however, we find that high school grades are not significant and the estimated effects for college grades are affected only slightly. (Interested readers may obtain these results from the author.) At least some reduction might be expected since high school and college grades may both be proxies for academic aptitude (not completely controlled for by college selectivity) and may also be substitute measures for some kinds of knowledge.

It might be expected that traits associated with achievement in undergraduate school and an M.A. program are even more closely related than traits associated with high school and undergraduate achievement. But Tables 1 and 3 suggest that the extent to which an individual masters graduate subjects affects his productivity, even if he has demonstrated the possession of traits associated with high grades, by getting high grades as an undergraduate, and vice versa. This does not support the hypothesis that college grades are serving simply as a proxy for noncognitive characteristics.

In contrast, assume that the relation between education and job performance is due to the acquisition of knowledge (of academic subject matter) during the educational process. It might be expected that given a measure of an individual's mastery of course work in college, an additional measure of how well he did in high school would not add much to an overall measure of his knowledge of academic subject matter. Knowledge acquired in college is likely to dominate that acquired in high school. Under this assumption, given college grades, high school grades would contribute little to explaining job performance, as was found. On the other hand, the subject matter content of courses in graduate school (say, a master's program in business) is likely to be considerably different from that of undergraduate courses, especially in the case of persons with an undergraduate degree in engineering. Thus we might expect to observe an additive effect on job performance, as was found (Table 1). It may be seen (Table 3) that the effect is stronger for engineering undergraduates than for business majors.

---

[18] This would appear to be true of the traits which Gintis contends are important, namely, subordinacy, discipline, cognitive versus affective modes of response, and motivation according to external reward.

The emphasis on affective traits has been supported elsewhere by observing that the coefficient on level of education in most regression equations is not reduced substantially when an "ability" measure is added to the regression (see Gintis). The implication is that this coefficient would be reduced much more if measures of relevant affective traits were introduced. This argument ignores not only the effect of occupational entry requirements but also individual differences in the mastery of academic subject matter. Although the findings of this study do not minimize the importance of nonacademic traits, they suggest that affective traits do not dominate academic aptitude and knowledge in their effect on the productivity of these college graduates.

C. *College as a Filter*

We can now consider the possibility that the higher educational system selects persons with productive (preexisting) traits, but does not enhance productive ability. The argument above suggests that the relation between academic achievement and job performance is not simply due to academic aptitude or to noncognitive traits associated with doing well in school.[29] Even among persons who we know had relatively high academic aptitude when they went to college, mastery of academic subject matter was related to job performance. And we have argued that the relationship seems not to be explained by preexisting affective traits which may be associated with doing well in school, given academic aptitude or intelligence. The evidence suggests that college education is not only a signal of productive ability, but in fact enhances this ability.

D. *Preassignment to Jobs with a Future*

Finally, it might be argued that persons from better schools and with better grades were initially assigned to positions with greater possibilities for advancement relative to their productive abilities than were persons with poorer grades and from lower quality colleges. The limited evidence available, however, does not lend much support to this possibility. It seems reasonable to assume that positive responses to the questions regarding initial job experience and supervisor tend to reflect a favorable initial position. According to the above hypothesis, a positive relation between college selectivity (or grades) and the initial supervisor index (or initial experience index) would be expected. But it may be seen in the tabulation below that the relevant correlations are quite small; one in fact is negative.

IV. Conclusions and Comparison with Other Studies

The hypothesis of no relation between academic achievement and job performance must be rejected for this sample of college graduates. The differences in estimated rates of salary increase by college selectivity and college grade point average are substantial. These findings are consistent with those of Weisbrod and Peter Karpoff, who related earnings to college class rank and college quality using a sample of employees of the American Telephone and Telegraph Company.[30] Although they were unable to control for other individual characteristics, their calculated salary index increases with both class rank and college quality.[31] If persons with the same level of education can be distinguished by the "quality" of their degrees, then surely there would be an even greater difference in job performance between persons with different levels of education; for example, high school versus college. The measures used in selection and certification are not only related to productive traits, but the evidence suggests that college education enhanced the productive capabilities of these persons. It has also been found that other individual characteristics seem just as important as academic attributes in the determination of job productivity.

---

[29] We can rule out consideration of productive traits not associated with academic achievement on the basis of the observation that persons who do better in school also do better on the job. There seems to be no reason to believe that colleges select persons with productive traits that are not related to academic achievement. For example, traits that may be associated with socioeconomic background appear to be unimportant when academic achievement is controlled for.

[30] The data used represented within-group means

Although not affording a direct comparison, the conclusions reached by the industrial psychologist Ghiselli, who used an entirely different approach, tend to parallel the findings here, especially with respect to the nonacademic variables. From studies of managers, he concluded that the following traits were of particular importance to managerial success: intelligence, supervisory ability, initiative, self-assurance, and perceived occupational level. In drawing comparisons with this study, it might be assumed that intelligence is loosely captured (along with knowledge) by college selectivity and grades and that supervisory ability is represented by the leadership index. Initiative, which he described as a "certain independence and inventiveness," has been assumed to be partially reflected in the initial experience (or initiative) index. Self-assurance, which he assumed to be possessed by an individual who perceives himself as being effective in dealing with problems or, who is "self confident," is likely to be inversely related to the job security index.[32] Finally, perceived occupational level, which may be a "level of aspiration," would presumably be affected by socioeconomic background, although this index was not significant in this study after controlling for other variables.

Without discussing the merits of research methodologies, some indication of the reasons for the apparent discrepancy between the conclusions of persons studying blue collar workers (for example, Berg) and the results suggested by this study is provided by Wolfle and Joseph Smith. They found that high school class rank—which might be taken as a measure of academic ability or achievement—had little to do with earnings twenty years later for persons who entered technical schools, had some college, or had no post-high school education, but was strongly related to earnings for those with one or more college degrees. Results pertaining to jobs not normally held by college graduates are likely to be considerably different from those reported here.

In conclusion, measures of academic achievement and ability used in the selection and certification process in higher education are not only related to the productivity of college graduates in this sample, but the results suggest that college education contributed to their productive ability. These findings lend support to the practice of selecting students on the basis of academic measures. But nonacademic attributes, largely independent of academic characteristics, have also been shown to affect productivity. The two groups seem to be of approximately equal

---

rather than individual observations, where the groups were defined by class rank, college quality, and years employed. College quality was defined by the "subjective assessment" of company personnel officers.

[31] A similar pattern was obtained in this study using the "salary index" but the results are not shown here.

[32] Ghiselli in fact says that: "Self-realization and autonomy universally are more important to managers than prestige, social satisfaction, and even security" (p. 237).

importance. In light of the use of the college degree as an occupational screening device, this suggests a second look at the practice of selecting persons for higher education solely or largely on the basis of academic aptitude or achievement. If persons were selected for higher education on the basis of their potential productivity in a chosen occupation, rather than their potential as future students, consideration of nonacademic as well as academic attributes would be necessary.

Transcendental Logarithmic Utility Functions

By LAURITS R. CHRISTENSEN, DALE W. JORGENSON, AND LAWRENCE J. LAU*

The traditional starting point for econometric studies of consumer demand is a system of demand functions giving the quantity consumed of each commodity as a function of total expenditure and the prices of all commodities. Tests of the theory of demand are formulated by requiring that the demand functions be consistent with utility maximization. Additive and homothetic utility functions have played an important role in formulating tests of the theory of demand. If the utility function is homothetic, expenditure proportions are independent of total expenditure. If the utility function is additive and homothetic, elasticities of substitution among all pairs of commodities are constant and equal.[1]

An example of the traditional approach to demand analysis is the system of double logarithmic demand functions employed in the pioneering studies of consumer demand by Henry Schultz, Richard Stone, and Herman Wold. If the theory of demand is valid and demand functions are double logarithmic, the utility function is linear logarithmic.[2] Similarly, the Rotterdam system of demand functions employed by A. P. Barten and Henri Theil is consistent with utility maximization only if the utility function is linear logarithmic.[3] A linear logarithmic utility function is both additive and homothetic; all expenditure proportions are constant, and elasticities of substitution among all pairs of commodities are constant and equal to unity.

Hendrik Houthakker and Stone have developed alternative approaches to demand analysis that retain the assumption of additivity while dropping the assumption of homotheticity.[4] Stone has employed a linear expenditure system, based on a utility function that is linear in the logarithms of quantity consumed less a constant for each commodity. The constants are interpreted as initial commitments; incremental expenditure proportions, derived from quantities consumed in excess of the initial commitments, are constant for all variations in total expenditure and prices. If all initial commitments are zero, the utility function is linear logarithmic in form. Nonzero commitments permit expenditure proportions to vary with total expenditure.

Houthakker has employed a direct addilog system, based on a utility function that is additive in functions that are homogeneous in the quantity consumed for each commodity. The degree of homogeneity may differ from commodity to commodity, permitting expenditure proportions to vary with total expenditure. If the degree of homogeneity is the same for all commodities, the addilog utility function is additive and homothetic. Robert Basmann, Leif Johansen, and Kazuo Sato have combined the approaches of Houthakker and Stone, defining each of the homogeneous functions in the direct addilog

---

* University of Wisconsin-Madison, Harvard University, and Stanford University, respectively.

[1] The class of additive and homothetic utility functions was first characterized by Abram Bergson.

[2] See Schultz, Stone (1954a), Wold, and Robert Basmann, R. C. Battalio, and J. H. Kagel.

[3] See Barten (1964, 1967, 1969), Daniel McFadden, and Theil (1965, 1967, 1971).

[4] See Houthakker (1960) and Stone (1954b). The linear expenditure system was originally proposed by Lawrence Klein and Herman Rubin.

utility function on the quantity consumed less a constant for each commodity. The resulting utility function is additive but not homothetic.[5]

Our first objective is to develop tests of the theory of demand that do not employ additivity or homotheticity as part of the maintained hypothesis. For this purpose we introduce new representations of the utility function in Section I. Our approach is to represent the utility function by functions that are quadratic in the logarithms of the quantities consumed. The resulting utility functions provide a local second-order approximation to any utility function. These utility functions allow expenditure shares to vary with the level of total expenditure and permit a greater variety of substitution patterns among commodities than functions based on constant and equal elasticities of substitution among all pairs of commodities.

Our second objective is to exploit the duality between prices and quantities in the theory of demand. A complete model of consumer demand implies the existence of an indirect utility function, defined on total expenditure and the prices of all commodities.[6] The indirect utility function is homogeneous of degree zero and can be expressed as a function of the ratios of prices of all commodities to total expenditure. The indirect utility function is useful in characterizing systems of direct demand functions, giving quantities consumed as functions of the ratios of prices to total expenditure. The direct utility function is useful in characterizing systems of indirect demand functions, giving the ratios of prices to total expenditure as functions of the quantities consumed. The system consisting of direct utility function and indirect demand functions is dual to the system consisting of indirect utility function and direct demand functions.[7]

We represent the indirect utility function by functions that are quadratic in the logarithms of ratios of prices to total expenditure, paralleling our treatment of the direct utility function. The resulting indirect utility functions provide a local second-order approximation to any indirect utility function. These indirect utility functions are not required to be additive or homothetic. The duality between direct and indirect utility functions has been used extensively in Houthakker's pathbreaking studies of consumer demand. Paralleling the direct addilog demand system, Houthakker has employed an indirect addilog system, based on an indirect utility function that is additive in ratios of prices to total expenditure.[8]

We refer to our representation of the direct utility function as the direct transcendental logarithmic utility function, or more simply, the *direct translog utility function*. The utility function is a transcendental function of the logarithms of quantities consumed. Similarly we refer to our representation of the indirect utility function as the indirect transcendental logarithmic utility function, or, more simply, the *indirect translog utility function*. Earlier, we introduced transcendental logarithmic functions into the study of production.[9] The duality between direct and indirect translog utility functions is analogous to the duality between translog production and price frontiers employed in our study of production.

---

[5] A recent survey of econometric studies of consumer demand is given by Alan Brown and Angus Deaton.

[6] The indirect utility function was introduced by Giovanni Antonelli, and independently by Harold Hotelling.

[7] Indirect demand functions were introduced by Antonelli. The duality between direct and indirect utility functions is discussed by Lau (1969a); the duality between systems of direct and indirect demand functions is discussed by Wold, John Chipman, and Leonid Hurwicz

[8] See Houthakker (1960). This demand system was originally proposed by Conrad Leser and has also been employed by W. H. Somermeyer, J. G. M. Hilhorst, and J. W. W. A. Wit.

[9] See the authors (1971, 1973).

For an additive direct utility function ratios of indirect demand functions, giving the ratios of prices, depend only on the quantities of the two commodities involved. The direct addilog and linear expenditure systems, together with the system employed by Basmann, Johansen, and Sato, have this property. Similarly, for an additive indirect utility function, ratios of direct demand functions giving the ratios of quantities depend only on the prices of the two commodities involved. The indirect addilog system has this property. For an additive and homothetic direct utility function the ratios of indirect demand functions depend only on the ratios of quantities. Furthermore, the indirect utility function is also additive and homothetic, so that ratios of direct demand functions depend only on ratios of prices. The use of direct and indirect translog utility functions permits us to test these restrictions on direct and indirect demand functions. We do not impose the restrictions as part of the maintained hypothesis.

We present statistical tests of the theory of demand in Section II. These tests can be divided into two groups. First, we test restrictions on the parameters of the direct translog utility function implied by the theory of demand. We test these restrictions without imposing the assumptions of additivity and homotheticity. We test precisely analogous restrictions on the parameters of the indirect translog utility function. Second, we test restrictions on the direct translog utility function corresponding to restrictions on the form of the utility function. In particular, we test restrictions corresponding to additivity and homotheticity of the direct translog utility function. Again, we test precisely analogous restrictions on the indirect translog utility function.

We present empirical tests of the theory of demand based on time-series data for the United States for 1929–72 in Section III. The data include prices and quantities consumed of the services of consumers' durables, nondurable goods, and other services. For these data we present direct tests of the theory of demand based on the direct translog utility function, and indirect tests of the theory based on the indirect translog utility function. For both direct and indirect tests we first test the extensive set of restrictions implied by the theory of demand. Proceeding conditionally on the validity of the theory, we test restrictions on the form of the direct and indirect utility functions implied by the assumptions of additivity and homotheticity.

I. Transcendental Logarithmic Utility Functions

A. *Direct Translog Utility Function*

The ***direct utility function U*** can be represented in the form:

$$\ln U = \ln U(X_1, X_2, \ldots, X_m) \tag{1}$$

where X_i is the quantity consumed of the ith commodity. The consumer maximizes utility subject to the budget constraint:

$$\sum p_i X_i = M \tag{2}$$

where p_i is the price of the ith commodity and M is the value of total expenditure.

The first-order conditions for a maximum of utility can be written:

$$\frac{\partial \ln U}{\partial \ln X_j} = \mu \frac{p_j X_j}{U} \quad (j = 1, 2, \ldots, m) \tag{3}$$

where μ is the marginal utility of income. From the budget constraint we obtain:

$$\frac{\mu}{U} = \frac{1}{M} \sum \frac{\partial \ln U}{\partial \ln X_i} \tag{4}$$

so that:

$$\frac{\partial \ln U}{\partial \ln X_j} = \frac{p_j X_j}{M} \sum \frac{\partial \ln U}{\partial \ln X_i} \quad (j = 1, 2, \ldots, m) \tag{5}$$

To preserve symmetry with our treatment of the indirect utility function given below, we approximate the negative of the logarithm of the direct utility function by a function quadratic in the logarithms of the quantities consumed:

$$(6)\quad -\ln U = \alpha_0 + \sum \alpha_i \ln X_i + \tfrac{1}{2}\sum\sum \beta_{ij} \ln X_i \ln X_j$$

Using this form for the utility function we obtain:

$$(7)\quad \alpha_j + \sum \beta_{ji} \ln X_i = \frac{p_j X_j}{M} \sum (\alpha_k + \sum \beta_{ki} \ln X_i) \qquad (j = 1, 2, \ldots, m)$$

To simplify notation we write:

$$(8)\quad \alpha_M = \sum \alpha_k$$

$$(9)\quad \beta_{Mi} = \sum \beta_{ki} \qquad (i = 1, 2, \ldots, m)$$

so that:

$$(10)\quad \frac{p_j X_j}{M} = \frac{\alpha_j + \sum \beta_{ji} \ln X_i}{\alpha_M + \sum \beta_{Mi} \ln X_i} \qquad (j = 1, 2, \ldots, m)$$

The budget constraint implies that:

$$(11)\quad \sum \frac{p_i X_i}{M} = 1$$

so that, given the parameters of any $m-1$ equations for the budget shares $p_j X_j / M$ $(j=1, 2, \ldots, m)$, the parameters of the mth equation, α_m and β_{mj} $(j=1, 2, \ldots, m)$, can be determined from the definitions of α_M and β_{Mj} $(j=1, 2, \ldots, m)$.

Since the equations for the budget shares are homogeneous of degree zero in the parameters, a normalization of the parameters is required for estimation. A convenient normalization for the parameters of the direct translog utility function is:

$$(12)\quad \alpha_M = \sum \alpha_i = -1$$

B. *Indirect Translog Utility Function*

The ***indirect utility function*** V can be represented in the form:

$$(13)\quad \ln V = \ln V\left(\frac{p_1}{M}, \frac{p_2}{M}, \ldots, \frac{p_m}{M}\right)$$

We determine the budget share for the jth commodity from the identity:[10]

$$(14)\quad \frac{p_j X_j}{M} = -\frac{\partial \ln V}{\partial \ln p_j} \Big/ \frac{\partial \ln V}{\partial \ln M} \qquad (j = 1, 2, \ldots, m)$$

Preserving symmetry with the direct utility function, we approximate the logarithm of the indirect utility function by a function quadratic in the logarithms of the ratios of prices to the value of total expenditure:

$$(15)\quad \ln V = \alpha_0 + \sum \alpha_i \ln \frac{p_i}{M} + \tfrac{1}{2}\sum\sum \beta_{ij} \ln \frac{p_i}{M} \ln \frac{p_j}{M}$$

Using this form for the utility function we obtain:

$$(16)\quad \frac{\partial \ln V}{\partial \ln p_j} = \alpha_j + \sum \beta_{ji} \ln \frac{p_i}{M} \qquad (j = 1, 2, \ldots, m)$$

$$(17)\quad -\frac{\partial \ln V}{\partial \ln M} = \sum\left(\alpha_k + \sum \beta_{ki} \ln \frac{p_i}{M}\right)$$

As before, we simplify notation by writing:

$$(18)\quad \alpha_M = \sum \alpha_k$$

$$(19)\quad \beta_{Mi} = \sum \beta_{ki} \qquad (i = 1, 2, \ldots, m)$$

so that:

$$(20)\quad \frac{p_j X_j}{M} = \frac{\alpha_j + \sum \beta_{ji} \ln \frac{p_i}{M}}{\alpha_M + \sum \beta_{Mi} \ln \frac{p_i}{M}} \qquad (j = 1, 2, \ldots, m)$$

---

[10] This is the logarithmic form of René Roy's Identity.

The budget constraint implies that given the parameters of any $m-1$ equations for the budget shares, the parameters of the mth equation, α_m and β_{mj} $(j=1, 2, \dots, m)$, can be determined from the definitions of α_M and β_{Mj} $(j=1, 2, \dots, m)$. As before, we can normalize the parameters so that:

$$\alpha_M = \sum \alpha_i = -1 \tag{21}$$

II. Testing the Theory of Demand

A. *Stochastic Specification*

The first step in implementing an econometric model of demand based on the direct translog utility function is to add a stochastic specification to the theoretical model based on equations for the budget shares p_jX_j/M $(j=1, 2, \dots, m)$. Given the disturbances in any $m-1$ equations, the disturbance of the remaining equation can be determined from the budget constraint. Only $m-1$ equations are required for a complete econometric model of demand.

B. *Equality and Symmetry*

We estimate $m-1$ equations for the budget shares, subject to normalization of the parameter α_M appearing in each equation at minus unity. If the equations are generated by utility maximization, the parameters β_{Mj} $(j=1, 2, \dots, m)$ appearing in each equation must be the same. This results in a set of restrictions relating the m parameters appearing in each of the $m-1$ equations, a total of $m(m-2)$ restrictions. We refer to these as *equality restrictions.*

The logarithm of the direct translog utility function is twice differentiable in the logarithms of the quantities consumed, so that the Hessian of this function is symmetric. This gives rise to a set of restrictions relating the parameters of the cross-partial derivatives:

$$\beta_{ij} = \beta_{ji} \quad (i \neq j;\ i, j = 1, 2, \dots, m) \tag{22}$$

There are $(1/2)(m-2)(m-1)$ restrictions of this type among the parameters of the $m-1$ equations we estimate directly and $m-1$ such restrictions among the parameters of the equations we estimate indirectly from the budget constraint. We refer to these as *symmetry restrictions.* The total number of symmetry restrictions is $(1/2)m(m-1)$.

If equations for the budget shares are generated by maximization of a direct translog utility function, the parameters satisfy equality and symmetry restrictions. There are $(1/2)m(3m-5)$ such restrictions.

C. *Additivity*

If the direct utility function U is *additive,* we can write

$$\ln U = F\left(\sum \ln U^i(X_i)\right) \tag{23}$$

where each of the functions U^i depends on only one of the commodities demanded X_i, and F is a real-valued function of one variable.

The parameters of the translog approximation to an additive direct utility function can be written:

$$-\frac{\partial \ln U}{\partial \ln X_i} = -F'\frac{\partial \ln U^i}{\partial \ln X_i} = \alpha_i \quad (i = 1, 2, \dots, m) \tag{24}$$

$$-\frac{\partial^2 \ln U}{\partial \ln X_i \partial \ln X_j} = -F''\frac{\partial \ln U^i}{\partial \ln X_i}\frac{\partial \ln U^j}{\partial \ln X_j} = \beta_{ij} \quad (k \neq j;\ i, j = 1, 2, \dots, m) \tag{25}$$

where the logarithmic derivatives,

$$F' = \frac{\partial \ln U}{\partial \ln U^i} \quad (i = 1, 2, \dots, m) \tag{26}$$

$$F'' = \frac{\partial^2 \ln U}{\partial \ln U^i \partial \ln U^j} \quad (i, j = 1, 2, \dots, m) \tag{27}$$

are independent of i and j.

Under additivity the parameters of the translog utility function satisfy the restrictions:

$$\beta_{ij} = \theta\alpha_i\alpha_j \qquad (i \neq j;\ i, j = 1, 2, \ldots, m) \tag{28}$$

where

$$\theta = -\frac{F''}{(F')^2} \tag{29}$$

We refer to these as *additivity restrictions.* The total number of such restrictions is $(1/2)(m-2)(m-1)$.

The translog approximation to an additive utility function is not necessarily additive. The direct translog utility function is additive if and only if $ln\ U$ can be written as the sum of m functions, each depending on only one of the quantities demanded. We refer to such a function as *explicitly additive.* Explicit additivity of the translog utility function implies the additivity restrictions given above and the additional restriction:

$$\theta = 0 \tag{30}$$

We refer to this restriction as the *explicit additivity restriction.* We note that the translog approximation to an explicitly additive function is explicitly additive.

D. *Homotheticity*

If the direct utility function is *homothetic,* we can write:

$$ln\ U = F(ln\ H(X_1, X_2, \ldots, X_m)) \tag{31}$$

where the function H is homogeneous of degree one.

The parameters of the translog approximation to a homothetic direct utility function can be written:

$$-\frac{\partial\, ln\ U}{\partial\, ln\ X_i} = \frac{\partial F}{\partial\, ln\ H}\, \frac{\partial\, ln\ H}{\partial\, ln\ X_i} = \alpha_i \qquad (i = 1, 2, \ldots, m) \tag{32}$$

$$-\frac{\partial^2\, ln\ U}{\partial\, ln\ X_i \partial\, ln\ X_j} = \left[\frac{\partial F}{\partial\, ln\ H}\, \frac{\partial^2\, ln\ H}{\partial\, ln\ X_i \partial\, ln\ X_j} + \frac{\partial^2 F}{\partial\, ln\ H^2}\, \frac{\partial\, ln\ H}{\partial\, ln\ X_i}\, \frac{\partial\, ln\ H}{\partial\, ln\ X_j}\right] = \beta_{ij} \qquad (i, j = 1, 2, \ldots, m) \tag{33}$$

Homogeneity of degree one of the function H implies that:

$$\sum \frac{\partial\, ln\ H}{\partial\, ln\ X_i} = 1 \tag{34}$$

$$\sum_{j=1}^{m} \frac{\partial^2\, ln\ H}{\partial\, ln\ X_i \partial\, ln\ X_j} = 0 \qquad (i = 1, 2, \ldots, m) \tag{35}$$

Under homotheticity the parameters of the translog utility function satisfy the restrictions:

$$\beta_{Mi} = \sigma\alpha_i \qquad (i = 1, 2, \ldots, m) \tag{36}$$

where

$$\sigma = \frac{\partial^2 F}{\partial\, ln\ H^2} \tag{37}$$

and we have used the normalization

$$\sum \alpha_i = -1 \tag{38}$$

We refer to these as *homotheticity restrictions.* There are $m-1$ such restrictions.

The translog approximation to a homothetic utility function is not necessarily homothetic. A necessary and sufficient condition for homotheticity of the translog utility function is that it is homogeneous, so that:

$$\sigma = 0 \tag{39}$$

We refer to this restriction as the *homogeneity restriction.* We note that the translog approximation to a homogeneous function is homogeneous.

E. *Additivity and Homotheticity*

The class of additive and homothetic direct utility functions coincides with the class of utility functions with constant elasticities of substitution among all commodities. If the direct utility function U is additive and homothetic, we can write:

$$\ln U = F\left(\sum \delta_i X_i^\rho\right) \tag{40}$$

or

$$\ln U = F\left(\sum \delta_i \ln X_i\right) \tag{41}$$

The second form is a limiting case of the first corresponding to unitary elasticities of substitution among all commodities.

The parameters of the translog approximation to an additive and homothetic utility function satisfy the additivity and homotheticity restrictions given above, so that:

$$\beta_{ij} = \theta\alpha_i\alpha_j \quad (i \neq j;\, i,j = 1, 2, \ldots, m) \tag{42}$$

$$\beta_{ii} = (\sigma + \theta)\alpha_i + \theta\alpha_i^2 \quad (i = 1, 2, \ldots, m) \tag{43}$$

where we have used the normalization

$$\sum \alpha_i = -1 \tag{44}$$

The translog approximation to an additive and homothetic utility function is not necessarily additive and homothetic. We can, however, identify the parameters of a translog approximation with the parameters of the additive and homothetic utility function given above, as follows:

$$\sigma + \theta = \rho \tag{45}$$

$$\alpha_i = \delta_i \quad (i = 1, 2, \ldots, m) \tag{46}$$

As before, the parameter θ corresponds to:

$$\theta = -\frac{F''}{(F')^2} \tag{47}$$

The translog approximation to a utility function characterized by unitary elasticities of substitution among all commodities satisfies the restriction:

$$\sigma + \theta = \rho = 0 \tag{48}$$

Under this restriction the expenditures shares are constant:

$$\frac{p_j X_j}{M} = \frac{\alpha_j + \theta\alpha_j \sum \alpha_i \ln X_i}{-1 - \theta \sum \alpha_i \ln X_i} = -\alpha_j \tag{49}$$

The value of the parameter θ is arbitrary so that we can let σ and θ be equal to zero. The translog approximation to a utility function with unitary elasticities of substitution has the same empirical implications as a linear logarithmic utility function, which is explicitly additive and homogeneous.

F. *Duality*

In implementing an econometric model of demand based on the indirect translog utility function the first step as before is to add a stochastic specification to the theoretical model based on equations for the budget shares $p_j X_j/M$ $(j=1, 2, \ldots, m)$. Only $m-1$ equations are required for a complete model. If equations for the budget shares are generated from the indirect translog utility function, the parameters satisfy equality and symmetry restrictions that are strictly analogous to the corresponding restrictions for the direct translog utility function.

Additivity and homotheticity restrictions for the indirect translog utility function are analogous to the corresponding restrictions for the direct translog function. The direct utility function is homothetic if and only if the indirect utility function is homothetic.[11] In general, an additive direct utility function does not correspond to an additive indirect utility function.[12] However, if the direct utility function is additive and homothetic, the indirect util-

[11] See, for instance, Paul Samuelson (1965) and Lau (1969b).

[12] See Lau (1969b).

ity function is additive and homothetic. Direct and indirect utility functions corresponding to the same preferences are additive only if the direct utility function is homothetic[13] or the direct utility function is linear logarithmic in all but one of the commodities.[14] In this relationship the roles of direct and indirect utility functions can be interchanged.

A direct utility function is *self-dual* if the corresponding indirect utility function has the same form.[15] The only direct translog utility function which is self-dual is the linear logarithmic utility function. Linear logarithmic utility functions are the only additive and homothetic direct or indirect translog utility functions. Translog direct and indirect utility functions represent the same preferences if and only if they are self-dual; that is, if and only if they are linear logarithmic. Unless this stringent condition is met, the direct and indirect translog approximations to a given pair of direct and indirect utility functions represent different preferences.

III. Empirical Results

A. *Summary of Tests*

We have developed statistical tests of the theory of demand that do not employ the assumptions of additivity and homotheticity for individual commodities or for commodity groups. At this point we outline restrictions on equations for the budget shares corresponding to direct and indirect translog utility functions. First, we present restrictions derived from the theory of demand; that is, from the basic hypothesis of utility maximization. Second, we present restrictions derived from hypotheses about functional form such as additivity and homotheticity.

Our empirical tests are based on data for three commodity groups—services of consumers' durables, nondurable goods, and other services—so that we specialize our presentation of statistical tests of the theory of demand to the three-commodity case, $m=3$. A complete econometric model for either direct or indirect translog utility functions is provided by any pair of equations for the budget shares. We consider the system of two equations,

$$\frac{p_1X_1}{M} = \frac{\alpha_1+\beta_{11}\, ln\, X_1+\beta_{12}\, ln\, X_2+\beta_{13}\, ln\, X_3}{-1+\beta_{M1}\, ln\, X_1+\beta_{M2}\, ln\, X_2+\beta_{M3}\, ln\, X_3} \tag{50}$$

$$\frac{p_2X_2}{M} = \frac{\alpha_2+\beta_{21}\, ln\, X_1+\beta_{22}\, ln\, X_2+\beta_{23}\, ln\, X_3}{-1+\beta_{M1}\, ln\, X_1+\beta_{M2}\, ln\, X_2+\beta_{M3}\, ln\, X_3} \tag{51}$$

corresponding to the direct translog utility function and the system of equations,

$$\frac{p_1X_1}{M} = \frac{\alpha_1+\beta_{11}\, ln\, \frac{p_1}{M}+\beta_{12}\, ln\, \frac{p_2}{M}+\beta_{13}\, ln\, \frac{p_3}{M}}{-1+\beta_{M1}\, ln\, \frac{p_1}{M}+\beta_{M2}\, ln\, \frac{p_2}{M}+\beta_{M3}\, ln\, \frac{p_3}{M}} \tag{52}$$

$$\frac{p_2X_2}{M} = \frac{\alpha_2+\beta_{21}\, ln\, \frac{p_1}{M}+\beta_{22}\, ln\, \frac{p_2}{M}+\beta_{23}\, ln\, \frac{p_3}{M}}{-1+\beta_{M1}\, ln\, \frac{p_1}{M}+\beta_{M2}\, ln\, \frac{p_2}{M}+\beta_{M3}\, ln\, \frac{p_3}{M}} \tag{53}$$

corresponding to the indirect translog utility function. Restrictions for the two systems are perfectly analogous so that the following outline may be applied to either system. We emphasize the fact that the two systems represent the same preferences if and only if

---

[13] See Houthakker (1960), Samuelson (1965), and Lau (1969b).

[14] This is the special case introduced by John Hicks. See also Samuelson (1969).

[15] See Samuelson (1965) and Houthakker (1965). We may also mention the "self-dual addilog system" introduced by Houthakker (1965). This system is not generated by additive utility functions except for special cases.

$$\beta_{ij} = 0 \qquad (i, j = 1, 2, 3) \tag{54}$$

1. *Equality Restrictions.* The parameters $\{\beta_{M1}, \beta_{M2}, \beta_{M3}\}$ occur in both equations and must take the same values. There are three equality restrictions.

2. *Symmetry Restrictions.* One restriction of this type is explicit in the two equations we estimate directly, namely,

$$\beta_{12} = \beta_{21} \tag{55}$$

In addition, we estimate the parameters β_{31} and β_{32} from the equations:

$$\beta_{31} = \beta_{M1} - \beta_{11} - \beta_{21} \tag{56}$$

$$\beta_{32} = \beta_{M2} - \beta_{12} - \beta_{22} \tag{57}$$

so that the two additional symmetry restrictions are implicit in the two equations we estimate. We write these restrictions in the form:

$$\beta_{13} = \beta_{M1} - \beta_{11} - \beta_{21} \tag{58}$$

$$\beta_{23} = \beta_{M2} - \beta_{12} - \beta_{22} \tag{59}$$

There are three symmetry restrictions altogether.

We can identify tests of the six equality and symmetry restrictions with tests of the theory of demand. We next consider tests of hypotheses about functional form.

3. *Additivity Restrictions.* Given the equality and symmetry restrictions, the additivity restrictions take the form:

$$\beta_{12} = \theta\alpha_1\alpha_2 \tag{60}$$

$$\beta_{13} = \theta\alpha_1(-1 - \alpha_1 - \alpha_2) \tag{61}$$

$$\beta_{23} = \theta\alpha_2(-1 - \alpha_1 - \alpha_2) \tag{62}$$

We introduce the additional parameter θ, so that there are two independent restrictions of this type.

4. *Homotheticity Restrictions.* Given the equality and symmetry restrictions, the homotheticity restrictions take the form:

$$\beta_{M1} = \sigma\alpha_1 \tag{63}$$

$$\beta_{M2} = \sigma\alpha_2 \tag{64}$$

$$\beta_{M3} = \sigma(-1 - \alpha_1 - \alpha_2) \tag{65}$$

We introduce the additional parameter σ, so that there are two independent restrictions of this type.

5. *Explicit Additivity Restrictions.* Given the equality, symmetry, and additivity restrictions, a translog utility function is explicitly additive under the further restriction:

$$\theta = 0 \tag{66}$$

6. *Homogeneity Restrictions.* Given the equality, symmetry, and homotheticity restrictions, the homogeneity restriction takes the form:

$$\sigma = 0 \tag{67}$$

7. *Linear Logarithmic Utility Restrictions.* Given the equality, symmetry, additivity, and homotheticity restrictions, the translog utility function reduces to linear logarithmic form under the additional restrictions:

$$\sigma = \theta = 0 \tag{68}$$

Tests of hypotheses about the form of the utility function can be carried out in a number of different sequences. We propose to test additivity and homotheticity in parallel. Each of these hypotheses consists of two independent restrictions. Our test procedure is presented in diagrammatic form in Figure 1. We also present alternative test procedures. For example, we could first test additivity and then test homotheticity only if additivity is accepted. Our test procedure is indicated with double lines while possible alternative procedures are indicated with single lines.

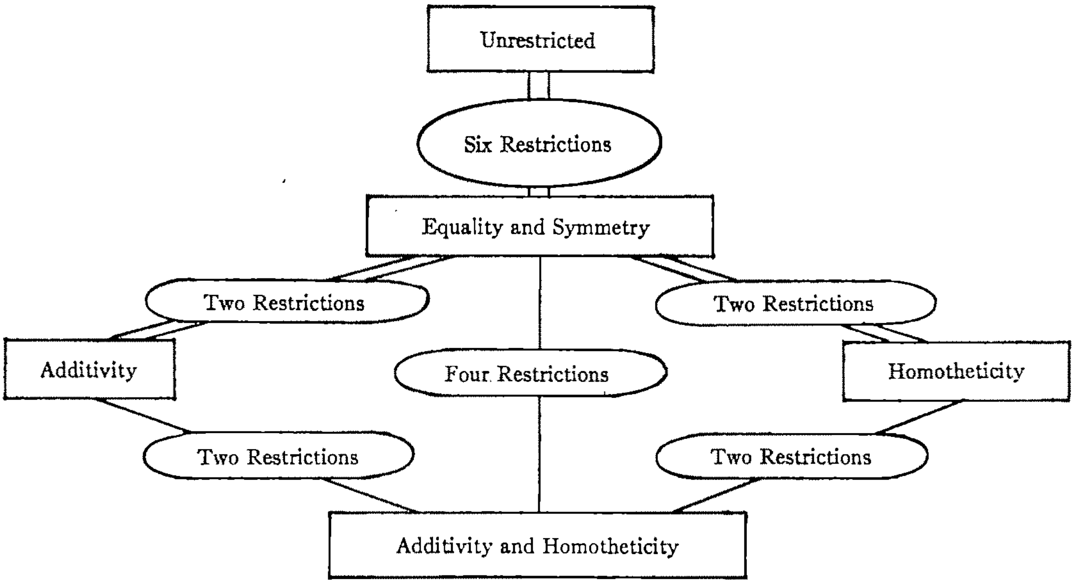

FIGURE 1. TESTS OF ADDITIVITY AND HOMOTHETICITY

The next step in our test procedure depends on the outcome of the tests of additivity and homotheticity. If we accept both additivity and homotheticity restrictions, we continue by testing explicit additivity and homogeneity in parallel. If we accept both hypotheses, we conclude that utility is linear logarithmic. A second possibility is that we accept additivity but reject homotheticity. In this case we continue by testing explicit additivity. The third possibility is that we accept homotheticity but reject additivity; we continue by testing homogeneity. If we reject both

additivity and homogeneity, we terminate the sequence of tests. These tests are presented diagrammatically in Figure 2.

B. *Estimation*

Our empirical results are based on time-series data for *U. S.* personal consumption expenditures for 1929–72. The data include prices and quantities of the services of consumers' durables, nondurable goods, and other services. We have fitted the equations for budget shares generated by direct translog and indirect translog utility functions, employing the stochastic specification outlined above. Under this specification only two equations are required for a complete econometric model of demand. We have fitted equations for the services of consumers' durables (durables) and for nondurable goods (nondurables). There are forty-four observations for each behavioral equation, so that the number of degrees of freedom available for statistical tests of the theory of demand is eighty-eight for either direct or indirect specification.

For both direct and indirect specifications the maintained hypothesis consists of the unrestricted form of the two behavioral equations for the budget shares. We estimate the behavioral equations for durables and nondurables by the method of maximum likelihood and derive estimates of the parameters of the behavioral equation for services, using the budget constraint.[16] The maximum likelihood estimates of the parameters of all three behavioral equations are invariant with respect to the choice of the two equations to be estimated directly.

The unrestricted behavioral equations, normalized so that the parameter α_M is minus unity in each equation, involve fourteen unknown parameters or seven unknown parameters for each equation. Unrestricted estimates of these parameters for the direct translog utility function are presented in the first column of Table 1. The first hypothesis to be tested is that the theory of demand is valid; to test this hypothesis we impose the six equality and symmetry restrictions. Restricted estimates of the fourteen unknown parameters are presented in the second column of Table 1. Unrestricted and restricted estimates of the fourteen unknown parameters for the indirect translog utility function are presented in the first and second columns of Table 2.

Given the validity of the theory of demand, the remaining hypotheses to be tested are restrictions on the functional form. First, we test the hypothesis that the direct utility function is additive; this hypothesis requires that we impose two additional restrictions. The corresponding restricted estimates of the unknown parameters for the direct translog utility function are given in the third column of Table 1. Second, we test the hypothesis that the direct utility function is homothetic without imposing the additivity restrictions; this hypothesis requires two restrictions in addition to the equality and symmetry restrictions. The restricted estimates of the unknown parameters for the direct translog utility function are given in the fourth column of Table 1. Finally, we impose both additivity and homotheticity restrictions, obtaining the restricted estimates presented in the fifth column of Table 1. The corresponding restricted estimates for the indirect translog utility function are given in the third, fourth, and fifth columns of Table 2.

The next stage of our test procedure is contingent on the outcome of our tests of

---

[16] We employ the maximum likelihood estimator discussed, for example, by Edmond Malinvaud, pp. 338–41. In the computations we use the Gauss-Newton method described by Malinvaud, p. 343. For the direct series of tests we assume that the disturbances are independent of the quantities consumed. For the indirect series of tests we assume that the disturbances are independent of the ratios of prices to the value of total expenditure.

additivity and homotheticity. If we accept additivity, but not homotheticity, we test explicit additivity by imposing one further restriction. If we accept homotheticity, but not additivity, we test homogeneity by imposing one further restriction. The restricted estimates under these restrictions are given in the sixth and seventh columns of Table 1. The corresponding estimates for the indirect translog utility function are given in the sixth and seventh columns of Table 2.

If we accept both additivity and homotheticity hypotheses, we test the hypothesis that the direct utility function is explicitly additive by imposing one further restriction. Similarly, we test homogeneity by imposing one further restriction. Finally, we impose both restrictions under the hypothesis that utility is linear logarithmic. The restricted estimates under each of these sets of restrictions are given in the eighth through tenth columns of Table 1. The corresponding restricted estimates for the indirect translog utility function are given in the eighth through tenth columns of Table 2. The direct and indirect translog utility functions are self-dual if they are linear logarithmic, so that restricted estimates for the two alternative econometric models given in the final columns of the two tables are identical.

C. *Test Statistics*

To test the validity of restrictions implied by the theory of demand and restrictions on the form of the utility function, we employ test statistics based on the likelihood ratio λ, where:

$$\lambda = \frac{\max_{\omega} \mathcal{L}}{\max_{\Omega} \mathcal{L}} \tag{69}$$

The likelihood ratio is the ratio of the maximum value of the likelihood function $\mathcal{L}$ for the econometric model of demand ω subject to restriction to the maximum value of the likelihood function for the model Ω without restriction. For normally distributed disturbances the likelihood ratio is equal to the ratio of the determinant of the restricted estimator of the variance-covariance matrix of the disturbances to the determinant of the unrestricted estimator, each raised to the power $-(n/2)$.

Our test statistic for each set of restrictions is based on minus twice the logarithm of the likelihood ratio, or:

$$(70)\quad -2ln\lambda = n(ln\ |\hat{\Sigma}_\omega| - ln\ |\hat{\Sigma}_\Omega|)$$

where $\hat{\Sigma}_\omega$ is the restricted estimator of the variance-covariance matrix and $\hat{\Sigma}_\Omega$ is the unrestricted estimator. Under the null hypothesis this test statistic is distributed, asymptotically, as chi-square with number of degrees of freedom equal to the number of restrictions to be tested.

To control the overall level of significance for each series of tests, direct and indirect, we set the level of significance for each series at .05. We allocate the overall level of significance among the various stages in each series. We first assign a level of significance of .01 to the test of equality and symmetry restrictions implied by the theory of demand. We then assign a level of significance of .04 to tests of restrictions on functional form. These two sets of tests are "nested"; under the null hypothesis the sum of levels of significance provides a close approximation to the level of significance for both sets of tests simultaneously.

We test additivity and homotheticity in parallel, proceeding conditionally on the validity of the theory of demand. These tests are not nested so that the sum of levels of significance for each of the two hypotheses is an upper bound for the level of significance of tests of the two hypotheses considered simultaneously. There are four possible outcomes of our parallel tests of additivity and homotheticity: Reject both, accept both, accept only additivity, and accept only homotheticity. If we reject both hypotheses, our test procedure terminates. If we accept either or both of these hypotheses, we proceed to test explicit additivity or homogeneity, or both.

If we accept both additivity and homotheticity, we test explicit additivity and homogeneity in parallel, conditional on the validity of additivity and homotheticity. Again, the tests are not nested, so that the sum of levels of significance for the two tests provides an upper bound for the tests considered simultaneously. If we accept only additivity, we proceed to test explicit additivity, conditional on additivity. Similarly, if we accept only homotheticity, we proceed to test homogeneity.

Since our three alternative procedures for testing explicit additivity and homogeneity are mutually exclusive, we carry out tests of these hypotheses one time at most. We assign levels of significance to the four hypotheses—additivity, explicit additivity, homotheticity, and homogeneity—with the assurance that the sum of levels of significance provides an upper bound for the level of significance for all four tests. We assign a level of significance of .01 to each of the four hypotheses. With the aid of critical values for our test statistics given in Table 3 the reader can evaluate the results of our tests for alternative allocations of the overall levels of significance among stages of the test procedure.

Table 3—Critical Values of χ^2/Degrees of Freedom

Degrees of Freedom	Level of Significance .10	.05	.025	.01	.005
1	2.71	3.84	5.02	6.63	7.88
2	2.30	3.00	3.69	4.61	5.30
4	1.94	2.37	2.79	3.32	3.72
6	1.77	2.10	2.41	2.80	3.09

Test statistics for both direct and indirect tests of the theory of demand and of restrictions on functional form are presented in Tables 4 and 5. At a level of significance of .01 we reject the hypothesis that restrictions implied by the theory of demand are valid for either direct or indirect series of tests. With this conclusion we can terminate the test sequence, since these results invalidate the theory of demand.

One interesting alternative to our test procedure is to maintain the theory of demand and to test the validity of restrictions on the form of the utility function. Proceeding conditionally on the validity of the theory of demand, we could test the validity of restrictions on the form of the utility function. For the direct series of tests we would reject the restrictions implied by additivity and homotheticity. This conclusion would hold for our preferred procedure of testing these hypotheses in parallel, for a test of either hypothesis conditional on the validity of the

Table 4—Test Statistics for Direct and Indirect Tests of the Theory of Demand and Tests of Additivity and Homotheticity

Hypothesis	Degrees of Freedom	Direct	Indirect
Theory of Demand			
Equality and Symmetry	6	5.64	10.25
Given the Theory of Demand			
Additivity	2	33.63	2.95
Homotheticity	2	13.71	22.68

Additivity Given Homotheticity	2	24.33	9.81
Homotheticity Given Additivity	2	4.42	29.54

other, or for a joint test of the two hypotheses.

For the indirect series of tests we would reject the restrictions implied by homotheticity, but we would accept the restrictions implied by additivity at a level of significance of .01. For the direct series of tests, we could terminate the test sequence conditional on the theory of demand at this point. For the indirect series of tests, we could test the validity of explicit additivity, given additivity but not homotheticity. We would accept the hypothesis of explicit additivity, given additivity at a level of significance of .01, conditional on the validity of the theory of demand.

In previous econometric studies of demand, the theory of demand has been maintained together with the assumption of additivity. A second alternative to our test procedure is to maintain both the theory of demand and the restrictions implied by additivity. We can test homotheticity; for either direct or indirect series of tests we reject this hypothesis. Given additivity but not homotheticity, we would reject explicit additivity for the direct series of tests and accept explicit additivity for the indirect series of tests. Either of these sets of results would rule out linear logarithmic utility.

IV. Summary and Conclusion

Our objective has been to test the theory of demand without imposing the assumptions of additivity and homotheticity as part of the maintained hypothesis. For either the direct or the indirect series of tests, we conclude that the theory of demand is inconsistent with the evidence. These results confirm the findings of Wold (in association with Lars Juréen) for the double logarithmic demand system and Barten for the Rotterdam demand system.[17] At the same time our results provide the basis for more specific conclusions.

If the theory of demand were valid, the double logarithmic form for the system of demand functions would imply that the utility function is linear logarithmic. Similarly, the validity of the theory of demand and the Rotterdam form for the system of demand functions would imply linear logarithmic utility. An equally valid interpretation of the results of Wold and Barten is that the theory of demand is valid, but that utility is not linear logarithmic. Our results rule out this alternative interpretation and make possible an unambiguous rejection of the theory of demand.

A possible alternative to our test procedure is to maintain the validity of the theory of demand. Proceeding conditionally on the validity of demand theory, we would reject the hypothesis of additivity for the direct series of tests. Additivity of the direct utility function is employed as a maintained hypothesis by Houthakker in the direct addilog demand system, by Stone in the linear expenditure system, and by Basmann, Johansen, and Sato in the demand system incorporating features of both.

---

[17] See Wold, especially pp. 281–302; Barten (1969). A detailed review of tests of the theory of demand is given by Brown and Deaton, pp. 1188–95.

Again, proceeding conditionally on the validity of the theory of demand, we would accept the hypothesis of additivity for the indirect series of tests. This hypothesis is maintained by Houthakker in the implementation of the indirect addilog demand system. Additivity of the direct and indirect utility functions is mutually consistent if and only if the direct utility function is homothetic, so that the acceptance of additivity of the indirect utility function and the rejection of homotheticity rule out acceptance of additivity for the direct utility function.

Empirical Implications of Infrequent Purchase Behavior in a Stock Adjustment Model

By RICHARD B. WESTIN*

The major component of demand for established consumer durable goods is replacement investment. Various facets of replacement demand have been emphasized in modern studies of consumer durable goods expenditures. The most important consideration has been the necessity of relating depreciation of the service level of the currently held stock to the demand for new stock. This is commonly done in the familiar stock adjustment model of demand by assuming that replacement demand is proportional to net stock holdings.[1] Dale Jorgenson has provided a long-run theoretical basis for this assumption, but its use in empirical studies has been criticized by Martin Feldstein and David Foot for the case of business investment, and by Frank Wykoff (1970, 1973) for the case of automobiles.

Another facet of replacement demand which is often examined is that since service levels are relatively constant over moderate time periods, the timing of replacement of durable goods should be highly discretionary. This view is emphasized by Milton Friedman and has been used in many empirical studies, including recent papers by Saul Hymans and by F. Thomas Juster and Paul Wachtel. This approach is generally considered as an elaboration of the more mechanical stock adjustment approach, however, and the theoretical consistency of combining these models has not been questioned.

This study emphasizes a third facet of replacement demand that is critical to a correct model of the aggregate demand for consumer durables but which has generally been neglected. Individual purchasers of durable goods commonly enter the market only at infrequent intervals and are inactive the rest of the time. This means that the composition of the purchasing public changes in large measure from period to period, and this raises difficult questions of the correct basis for aggregation of the models. For example, the assumption that current replacement demand is equal to current depreciation on the entire existing stock of durables can no longer be justified. Many holders of durables have no intention of entering the market and do not translate the loss of services on their present stock into effective demand for new stock. I shall argue that a correct model of the aggregate demand for durables requires a reinterpretation of the role of substitution in use between new and old durables and an explicit distinction between planned and discretionary replacement.

Although the major question addressed in this paper is technical in nature, the

[1] For examples of the stock adjustment model applied to automobile demand, see papers by Gregory Chow, Daniel Suits and Gordon Sparks, Hendrik Houthakker and Lester Taylor, Michael Hamburger, and Ross Williams.

policy and forecasting implications of the issues raised are also important. Expenditures for consumer durables are a volatile component of national income, and they have proved to be one of the more difficult sectors to forecast. One implication of the argument raised in this paper is that the stock adjustment models typically used to forecast expenditures on consumer durables are severely biased with respect to the important policy parameters of income and price elasticities of demand. Moreover, the empirical model developed in this paper is directly tested vis-à-vis the stock adjustment model, and the extent of these biases will be demonstrated.

Section I examines the theoretical basis of replacement demand. I shall develop an alternative model of the demand for durable goods that will be conveniently referred to as the discretionary replacement model. Section II considers an empirical test of the discretionary replacement (*DR*) model against the stock adjustment (*SA*) model, and Section III discusses the policy implications of both models. For concreteness, the model is developed in the specific context of the demand for automobiles.

I. Theoretical Model

The theoretical basis for models in which consumers replace their durable goods only at infrequent intervals has been well established. If we assume lump sum transaction costs or imperfect secondhand markets, the optimal purchase policy for individuals is to enter the market only at lengthy intervals and to be inactive otherwise. For purposes of aggregate demand analysis, however, these models are useful only in justifying an approach based on a market where the composition of purchasers changes between periods; a direct derivation of our model from the optimal behavior of individuals would involve difficult assumptions on the distribution of preferences and stocks among individuals. The approach taken is to specify directly an aggregate model while paying particular attention to the empirical implications of infrequent purchase decisions.

To begin our derivation of the *DR* model, we first consider the simplest representation of normal replacement demand. It is assumed that the normal proportion of cars of a given age that will be replaced with new cars in each period is constant.[2] This means that the number of cars replaced with new cars in any year can be adequately predicted as:

$$N_t = \sum_{i=1}^{T} \alpha_i V_{t-i} \tag{1}$$

where N_t is the number of new cars purchased in time t, V_{t-i} is the number of cars of vintage t−i existing in period t, α_i is the proportion of cars of age i that are replaced with new cars, and T is the number of vintages.[3]

Equation (1) does not allow for the possibility of short-run variations in the normal timing of replacement. Consider the case where windfall gains induce some consumers to replace their automobiles one period earlier than they normally would. This would increase replacement demand in the period in which the windfalls occur and decrease replacement demand by the same amount in the next period when the consumers would normally have replaced their cars. To include the effects of short-run variables, the simplest way is to add the current values of these variables to equation (1) to get

---

[2] Replacements must be distinguished from scrappage. New car buyers generally replace cars that are less than five years old, while cars are scrapped much later. The occasionally used assumption that replacement will eventually cause some other car to be scrapped by a process of "bumping" requires an unrealistically rigid view of used car markets.

[3] Stock adjustment models generally use gross expenditures as their dependent variables, but cross-sectional studies (see papers by David Huang (1963, 1964), Maw Lin Lee, De-Min Wu, and John Cragg and Russell Uhler) have shown that the act of purchasing an automobile is determined by different considerations than the amount of gross expenditure on the automobile once the act of purchase has been decided. Our model therefore uses units purchased as the variable to be explained.

$$N_t = \sum_{i=1}^{T} \alpha_i V_{t-i} + \beta D_t \tag{2}$$

where D_t is a discretionary variable. If variations in replacement timing have occurred in previous periods, however, current demand must also reflect these variations. Under the assumption that discretionary variables change the timing of replacement by at most one year in either direction from the consumer's normal replacement date, an adequate procedure for accounting for the previous period's discretionary behavior is to subtract it from current replacement demand to get

$$N_t = \sum_{i=1}^{T} \alpha_i V_{t-i} + \beta(D_t - D_{t-1}) \tag{3}$$

If discretionary variables affect the timing of replacement by more than one period, then a weighted average of past discretionary variables must be subtracted from equation (3).

To understand equation (3), we consider the effects of a windfall gain in period t. The direct effect would be that some consumers who would normally replace their cars in later periods would replace them in period t, earlier than they had planned, and we get equation (2). In period t+1, however, assuming no further windfall gains, equation (2) would predict a return to normal replacement levels when in actuality some of the normal replacement that should have occurred in period t+1 has already occurred in period t. We would therefore expect a fall in purchases in period t+1 below normal replacement levels, and this is accounted for in equation (3). In period t+2, if no further windfall gains or losses occur, the market would return to normal replacement demand.

Replacement demand is important, but it is not a sufficient explanation of total demand. We must also account for nonreplacement demand which encompasses new entrants into the automobile market, increasing multiple car ownership among existing owners, and families that "trade up" to become new car buyers. Nonreplacement demand is assumed to be determined by observable economic variables such as income and relative prices, and by the existing stock of cars which represents a saturation effect on the market for new owners. Preserving the linear form of our specification gives us a final demand equation of the form:

$$N_t = N_t^* + \sum_{i=1}^{T} (\alpha_i - \gamma_i) V_{t-i} + \beta(D_t - D_{t-1}) \tag{4}$$

where N_t^*, nonreplacement demand, is a function of observable economic variables, and γ_i represents the saturation effect of the existing stock on nonreplacement demand.

The discretionary replacement model has been deliberately constructed in such a way that it is directly testable against the traditional stock adjustment model. Since contrasting these two models will clarify the theoretical role of a market where the composition of purchasers changes between periods, we turn briefly to the *SA* model before proceeding. The familiar *SA* model is expressed as:

$$A_t = \theta(S_t^* - S_{t-1}) + R_t \tag{5}$$

where A_t is new purchases in period t measured either as gross investment or as the number of units purchased; S_t^* consumers' desired net stock is a function of observable economic variables; S_{t-1} is existing undepreciated stock at the end of period t−1, measured either as net stock or the number of units in existence; R_t replacement demand in period t makes good the depreciation of the net stock; and θ is a constant between zero and one. Under the assumption that depreciation occurs at a constant rate $(1-k)$, equation (5) can be rewritten as

$$(6) \quad A_t = \theta S_t^* + (1 - k - \theta) \sum_{i=0}^{\infty} k^i A_{t-i-1}$$

Comparing the *DR* model (equation (4)) with the *SA* model (equation (6)), we note that aside from minor differences in the dependent variables and the interpretations of the coefficients, the two equations are equivalent except for the addition of the term $\beta(D_t - D_{t-1})$ to equation (4). As current discretionary variables have also been included in traditional *SA* models of new car demand, this means that the unique feature of the *DR* model is the inclusion of lagged discretionary variables which are specified to have an effect opposite in sign and equal in magnitude to current discretionary variables.[4] Since these variables are at the core of our criticism of *SA* models, it is necessary to contrast the assumptions of both models to justify our empirical tests.

The *SA* model is generally justified by an implicit model of continuous adjustment behavior in which the existing stock of durables has both a positive and negative effect on the demand for new durables—positive because of the necessity to replace the existing stock as it wears out and negative because it provides a substitute in use for new durables. Although the *SA* and *DR* models differ in measuring the first of these effects (i.e., whether to use depreciation or replacement patterns), the crucial difference between the models is in the concept of substitution in use between existing stocks and new durables, which is generally known as the inventory effect.

The inventory effect of existing stock on purchase rates is indeed powerful. The important distinction, however, is that its role is not to slow the rate of net investment in a continuous adjustment model but rather to preclude many consumers from entering the market at all in any given time period. More concretely, if car owners who own very new cars will not enter the market again for a long period of time, their holdings of stock are irrelevant for a prediction of demand in the near future since these consumers are effectively removed from the market. It is at this point that we encounter the distributional effects of a market where the composition of purchasers changes from period to period. The *SA* model specifies that very new used cars have a powerful depressing effect on current expenditures because they provide a substitute in use, but the fact that potential new car purchasers are not the same people as those who recently bought cars means these substitution possibilities do not exist. In contrast, the *DR* model we have proposed says that because we shift to a new group of potential purchasers, the stock of very new used cars is irrelevant for an explanation of demand, save for the relatively minor effects of some normal replacement demand and the saturation effect on nonreplacement demand.

Extensive empirical experience with the *SA* model indicates that equation (6), in which the existing stock has a negative effect on demand that decreases in absolute magnitude with age, provides a good explanation of demand. In the *DR* model, the saturation effect of the existing stock on nonreplacement demand makes the signs of the coefficients of existing stock indeterminant, but qualitatively our emphasis on replacement demand implies that the coefficients of existing stock might be expected to be positive or close to zero. Since this hypothesis on the coefficients is in contradiction to the known empirical results of the *SA* model, it is necessary to give a theoretical reason why existing stock has been consistently found to have a strong negative influence.

---

[4] Juster and Wachtel derive a stock adjustment model in which both current and lagged discretionary variables enter as separate variables with coefficients specified to be opposite in sign. The occurrence of the lagged discretionary variables in their equation is a result of the reduction of their structural model to a reduced form before estimation, however, and the coefficients of the lagged discretionary variables are overidentified in terms of the structural parameters of the stock adjustment model.

As we emphasize, the major difference between the models is that the *SA* model omits the lagged values of discretionary variables, which in our model represent the effects of past variations in planned replacement behavior. If the *DR* model correctly describes aggregate demand, the effect of omitting the lagged discretionary variables in the *SA* model is to bias the coefficients of the other variables, particularly those variables most highly correlated with the omitted variables. Since one-period lagged discretionary variables are also a determinant of one-period old stock, we would expect the newest existing stock variables to exhibit the maximum correlation with the lagged discretionary variables, and hence the coefficients of the newest existing stock variables should suffer the maximum bias when lagged discretionary variables are omitted from the the equation. Furthermore, since the effect of lagged discretionary variables on current purchases is postulated to be opposite in sign to their previous period's effect on purchases, the bias in the coefficient of one-period lagged stock would be negative. More concretely, our model postulates that windfall gains would have a positive effect on purchases in the current period and a negative effect in the next period. If one-period lagged windfall gains are omitted from the equation, their effect would be represented by a negative coefficient on one-period lagged stock. We therefore argue that the consistent finding of negative stock coefficients for the *SA* model may not be due to the inventory effect of existing stock on new purchases, but rather is due to the fact that existing stock variables are serving as proxy variables for omitted lagged discretionary variables.

These last considerations suggest an empirical test of the two proposed models. Instead of entering discretionary variables as first differences in equation (4), they can be entered independently and their separate contribution estimated. If the *SA* model is correct in that automobile demand is dominated by the inventory effect of existing stock, we would expect the coefficients of lagged discretionary variables to be insignificantly different from zero and the coefficients of existing stock variables to be negative and decreasing in absolute magnitude for older cars. On the other hand, if the correct model is the *DR* model, which emphasizes replacement demand and the effects of short-run variations in purchase timing, then the coefficients of lagged discretionary variables should be opposite in sign and roughly equal in magnitude to the coefficients of current discretionary variables and the coefficients of existing stock variables should be positive or close to zero. We turn now to our empirical results.

II. Empirical Results

The models specified in the previous section were estimated using annual data for the period 1953–72, with data from 1951 and 1952 used to give starting values of the lagged discretionary variables. The dependent variable was total new passsenger car retail sales.[5]

---

[5] These data unfortunately include business purchases of passenger cars. The alternative of using deflated expenditures data from the *Survey of Current*

The discretionary variables used in this study were the unemployment rate, the Survey Research Center Index of Consumer Sentiment, and transitory income; these variables have an extensive history of use in automobile demand studies (see, for example, Irwin Friend and F. Gerald Adams, Hymans, and Juster and Wachtel.)[6,7] The variables used to explain nonreplacement demand were disposable and permanent income and the relative price of new automobiles. The coefficients of the lagged stock variables in the regressions reported here were constrained to lie on a third-degree polynomial with the side restriction that the polynomial equal zero after seven periods. All equations have been reestimated under alternative specifications on the length and degree of the polynomial restriction, including the direct entry of the lagged stock variables; none of the substantive conclusions of this paper was affected by the use of the polynomial restriction.[8] Finally, a dummy variable representing strikes was added to all equations.

Table 1 summarizes the regression results for the models discussed in the last section. In order to judge the contribution of the lagged stock variables to the estimated equations, the F-statistic is used to test the hypothesis that the coefficients of the lagged stock variables all equal zero. The values of the F-statistic are reported in Table 1 under the heading "partial F." In addition, a key test of the *DR* model is the hypothesis that the coefficient of a lagged discretionary variable should be opposite in sign and equal in magnitude to the coefficient of the current value of that discretionary variable; the values of the t-statistic used to test this hypothesis are presented in Table 2.

Results 1, 2, and 3 in Table 1 correspond to the *SA* model, and they are compatible with the a priori predictions of that model. In all three results, the lagged stock variables make a significant contribution to the explained variation, and their estimated coefficients are large and negative and (once current discretionary variables are included) decline in absolute value for older stock.

Results 4–11 in Table 1 provide a test of the *DR* model we have proposed. Result

---

Business does not solve this problem, as the adjustment made for business expenditures in the *OBE* data is to reduce gross expenditures by a constant 17 percent (see Lawrence Grose and Edward Bassett).

[6] Current and lagged values of first differences of the discretionary variables were also tested to see whether effects of discretionary variables were best measured as deviations from long-run averages (implying the use of gross values of the variables) or as deviations from immediate past values (implying the use of the first differences); the former alternative fit the data better. Weighted averages of one- and two-period lagged discretionary variables were tried in order to investigate the hypothesis that short-run variations in replacement behavior affect purchases over a period of more than one year; the attitudes variable was improved by putting more weight on two-period lagged values, but these results are not reported here. I also tested the 4–6 month prime commercial paper rate as a representation of credit conditions but it performed poorly, probably because it represented a nominal rather than a real interest rate. Finally, lagged income and price variables were included to test the extent to which they contain discretionary influences, but the results were insignificant in the presence of other variables.

[7] Papers by Chow, Houthakker and John Haldi, and Wu argue that since the regression coefficient of current transitory income is not significantly different from the regression coefficient of permanent income in their studies, the division of disposable income into permanent and transitory components is irrelevant. This conclusion misses the essential point of Friedman's argument, which is that transitory income affects purchase timing while permanent income affects gross investment. The key issue is therefore not whether current transitory income has the same impact on purchases as permanent income, but whether *lagged* transitory income has an equal and opposite effect to current transitory income on purchases, an effect postulated by the *DR* model.

[8] It can be argued that this polynomial restriction forces any bias that occurs in the coefficient of one-period lagged stock to be transmitted to the coefficients of the other lagged stock variables. This effect occurs in the *SA* model when depreciation rates or scrappage rates are used to construct the stock variable, so a polynomial restriction on the coefficients is a compromise between the rigid weights of the *SA* model and the flexible pattern of the *DR* model.

UE, UE_{-1}, ΔUE = unemployment rate (current, lagged, first difference)
ATT, ATT_{-1}, ΔATT = Index of Consumer Sentiment (current, lagged, first difference)
YT, YT_{-1}, ΔYT = transitory income (current, lagged, first difference)
V_{-i} = number of cars in use on January 1 of vintage i years old
$STRIKE$ = dummy variable for strikes

[a] The figures in parentheses are t-ratios; $\hat{\rho}$ is the estimated autocorrelation coefficient.
[b] Denotes significance at the 10 percent level.
[c] Denotes significance at the 5 percent level.

4 provides strong confirmation of this model; the regression coefficient of the lagged unemployment rate is opposite in sign to the coefficient of the current value of the unemployment rate, and the test statistics show that we can strongly reject the null hypothesis that the coefficient of the lagged unemployment rate is equal to zero while we cannot reject (by Table 2) the hypothesis that the coefficient is equal in magnitude and opposite in sign to the coefficient of the current unemployment rate. Furthermore, the coefficients of the lagged stock variables are positive for the newest stock, and the partial F-test indicates that the stock variables in total do not make a significant contribution to the explained variation of this equation. These considerations on the coefficients of the stock variables are important because the sign and magnitude of the coefficient of the lagged unemployment rate could be

justified in a *SA* model in which the first difference in the unemployment rate determined desired stock. In this case, however, the coefficients of the lagged stock variables should still be negative and decline in absolute value as the stock gets older, so the coefficients of the lagged stock variables in result 4 of Table 1 indicate this hypothesis is not valid.

Although entering the unemployment rate as a discretionary variable produces results which are strongly compatible with the *DR* model, when the Index of Consumer Sentiment was entered as the only discretionary variable the results favored the *SA* model. The residuals of the equation showed negative autocorrelation was present, however, and because discretionary variables are postulated to enter with both current and lagged values and with coefficients opposite in sign in the *DR* model, negative autocorrelation indicates an alternative discretionary variable was omitted. We therefore reestimated the equation by maximum likelihood methods assuming a first-order Markov process for the error terms.[9] The results are given as 5 in Table 1 and favor neither model strongly. Rather than pursue the question of autocorrelation further, however, it is more important to identify the omitted discretionary variables, and we turn to the next equation.

Result 6 in Table 1, where current and lagged values of both the unemployment rate and the Index of Consumer Sentiment are entered as separate variables, is a severe drain on the available degrees of freedom, and the test statistics on the coefficients are inconclusive. The magnitudes of the coefficients, however, are most compatible with the *DR* model. We then entered the discretionary variables as first differences in result 7. This gives the formulation originally derived as the specification of the *DR* model and requires the same number of coefficient estimates as the *SA* model with current discretionary variables included; the models can then be compared by examining results 2 and 7 in Table 1. We find that entering the discretionary variables as first differences gives coefficients of the lagged stock variables that are small and positive for the newest stock; these results are consistent with the *DR* model and inconsistent with the *SA* model. Furthermore, by examining the goodness of fit statistics, R^2, and the standard error of the equation, we see that the *DR* model has a slightly better fit to the data than the *SA* model. The small difference in goodness of fit between the two models is not surprising. Our earlier discussion of the possible bias in the *SA* model emphasized that the newest lagged stock variables would be efficient proxies if the lagged discretionary variables were omitted. The important point is that the *DR* model achieves as good a fit as the traditional *SA* model while implying that the powerful inventory effect postulated by the *SA* model is

TABLE 2—TEST STATISTICS ON SUMS OF COEFFICIENTS[a]

Regression Result	Discretionary Variables		
	UE and UE_{-1}	ATT and ATT_{-1}	YT and YT_{-1}
4	1.57		
5		2.58**	
6	0.41	0.67	
8	1.41		0.11
9		2.18*	−0.17
10	0.41	0.72	−0.20

[a] t-statistics for the null hypothesis that the sum of the regression coefficients for the current and the lagged values of a discretionary variable equals zero. The symbol * denotes the hypothesis is rejected at the 10 percent significance level; the symbol ** denotes rejection at the 5 percent significance level.

---

[9] The test statistics of results 5 and 9 in Tables 1 and 2 are overstated as they do not correct for the fact that the autocorrelation parameter has been estimated (see J. Phillip Cooper).

insignificant. We have therefore found that the a priori predictions of the *DR* model are borne out by the data.

The rest of the results in Table 1, 8 through 11, repeat those discussed above with a measure of permanent income substituted for disposable income and transitory income treated as a discretionary variable. The results are compatible with their counterpart equations discussed above and we will not discuss them in depth other than to observe that again the results are more compatible with the *DR* model than the *SA* model.

Before turning to the policy implications of the *DR* model, we note that the bias we have been discussing would also exist for other versions of the *SA* model that eliminate most of the lagged stock variables from the equations to be estimated. Under the assumption that depreciation on the existing stock occurs at a constant rate, Marc Nerlove and Houthakker and Taylor show that the *SA* model can be transformed to eliminate all existing stock variables other than one-period lagged purchases. As should be clear from our discussion, however, the bias from omitting lagged discretionary variables centers mainly on one-period old stock, so the results of these models would still be biased. To test this claim, we estimated *SA* models in the Nerlove and Houthakker and Taylor forms with current and lagged discretionary variables included. Rather than examine these results in detail, it is sufficient to examine the estimated depreciation rates implied by the models. If the *SA* model is correct, the estimated depreciation rate should lie in the range of 20 to 30 percent on an annual basis, which contains the rates estimated from used car price data (see Chow and Wykoff (1970)). On the other hand, if the *DR* model correctly explains purchase behavior, one can argue that the estimated depreciation rate would be higher when lagged discretionary variables are included. Referring to the *SA* model, equation (6), we see that small values of k (which equals one minus the depreciation rate) would imply small coefficients attached to the lagged stock variables, which is predicted by the *DR* model. Since the Nerlove and Houthakker and Taylor models are basically a transformation of equation (6) where k is estimated, one would therefore expect that adding current and lagged discretionary variables to equation (6) and applying the transformation would yield a small value of k and hence a high depreciation rate if the *DR* model is correct.

When the *SA* model in the Nerlove form was estimated on our data with current discretionary variables included, the estimated depreciation rate ranged from 5 to 30 percent on an annual basis, which is compatible with the predictions from used car prices.[10] When lagged discretionary variables were included, the estimated depreciation rate jumped to a range of 45 to 70 percent on an annual basis. Since this is what one would expect when the inclusion of lagged discretionary variables removes the downward bias in the estimated effect of lagged stock variables, it is clear that the Nerlove and Houthakker and Taylor versions of the *SA* model do not escape the bias discussed here. We turn now, therefore, to the policy implications of our results.

III. Policy Implications

Up to this point, we have emphasized the bias in the regression coefficients of existing stock variables in the *SA* model caused by a neglect of short-run discretionary replacement activity. From an economic policy standpoint, however, the major interest in estimating demand equations would be on the effect of income and prices, as existing stock variables are not subject to exogenous control. If we examine closely the two models considered in the preceding section, we find that the biases are not limited solely to the coefficients of the stock variables but also affect our estimates of other key parameters. In particular, we will show that estimated demand elasticities with respect to income and prices are sensitive to the model specification we choose.

---

[10] The attitudes variable was omitted from these tests as it predicted an absurdly high depreciation rate for the *SA* model. Results of tests on the Houthakker and Taylor model were similar to that of the Nerlove model.

Discretionary purchase behavior causes short-run variations in purchases, but automobile purchases have also shown a long-term upward trend because of new entrants into the automobile market. Of the independent variables we have used in our empirical analysis, the discretionary variables have shown no strong trend in this period, nor has the relative price of new cars; the independent variables that do show a trend are the two income measures and the lagged stock variables. As the lagged stock variables are postulated to have either a negative effect (*SA* model) or a small effect (*DR* model) on purchases, the brunt of the explanation of the upward trend in automobile purchases must be incorporated into the regression coefficient of disposable or permanent income. The overall growth trend implied by the equation is then determined by the extent to which the upward trend in purchases caused by the growth of income is offset by the effects of growth of existing automobile stocks. This overall growth trend can be summarized by examining the long-run elasticity of purchases with respect to income, which is computed as

$$\left[b \Big/ \left(1 - \sum_{i=1}^{T} a_i\right)\right] \frac{\text{income}}{\text{purchases}} \tag{7}$$

where b is the estimated regression coefficient of disposable or permanent income and $\sum_{i=1}^{T} a_i$ is the sum of the estimated regression coefficients of the lagged stock variables (V_{-i}).

TABLE 3—AVERAGE PURCHASE ELASTICITIES[a]

	Income Elasticities		Price Elasticities	
	Long-run	Short-run	Long-run	Short-run
Stock Adjustment Model[b]	0.68	1.46	0.64	1.32
Discretionary Replacement Model[c]	0.52	0.72	1.26	1.65

[a] Elasticities are evaluated at the sample means of the variables.
[b] Results 1–3, Table 1.
[c] Results 4–11, Table 1.

Since the actual growth trend in purchases is implicit in the data, we would expect all the results reported in Table 1 to show roughly the same long-run income elasticity. This can be verified by examining the average purchase elasticities reported in Table 3; the estimated long-run elasticity of new car purchases with respect to income is similar for both the *DR* and *SA* models. On the other hand, the short-run elasticity of new car purchases with respect to income is very much higher for the *SA* model than the *DR* model. This elasticity is defined as $b \cdot (\text{income}/\text{purchases})$ and depends only on the regression coefficient of income. Now as the estimated coefficients of the lagged stock variables are biased downwards in the *SA* model, equation (7) shows that the regression coefficient of income must be biased upwards to preserve the long-term growth trend implied by the equation.[11] This means that estimates of short-run income elasticities, an important policy parameter in short-run stabilization questions, will be biased upwards in the *SA* model.

---

[11] More formally, if a variable is omitted from a linear regression, the bias in the coefficients of the included variables is proportional to the coefficients that would be obtained in a linear regression of the omitted variables on the included variables. Regressions we performed of the lagged discretionary variables on the other explanatory variables verified the strength and direction of the multiple biases discussed in this section of the text.

Turning to the long- and short-run price elasticities, we would not expect the regression coefficient of relative price to be seriously affected by a change from a *SA* model to a *DR* model because there is no clear correlation between prices and lagged discretionary variables. Because the coefficients of the lagged stock variables are biased downward in a *SA* model, however, we would expect the corresponding long-run price elasticity to be understated. This is what we observe in Table 3, where the average long-run price elasticity for the *SA* model is significantly below that of the *DR* model. Indeed, we observe that both the long- and short-run price elasticities for the *DR* model are above unity, which contradicts the usual finding of the *SA* model.

IV. Summary

This paper has argued that the appropriate theoretical specification for aggregate demand models for consumer durables must be a discrete purchase model rather than a continuous adjustment model. The key issue is the concept of substitution in use between new and old durables. In order to assume that very new used stock depresses new purchases because it is a good substitute in use requires the strong assumption that the distribution of stock among individuals is irrelevant. Alternatively, we can realize that recent purchasers are not the same people as those currently entering the market, and the stock holdings of recent purchasers are irrelevant for predicting current demand. Our empirical emphasis on discretionary variables in this paper has then come about because of the statistical problems of distinguishing discretionary replacement behavior from the inventory effect of existing stocks.

The discretionary replacement model proposed here requires data on existing stocks by vintages. Except for automobiles, these data are rarely available except as an extrapolation of purchase data. Our empirical work has found, however, that in terms of explaining the statistical variation of purchases over time, the data on existing stocks are unimportant. This is not surprising; the role of stock in the discretionary replacement model is basically an echo effect, and the echo effect is weak, even for automobiles. The surprising implication for forecasting is that existing stocks are relatively unimportant statistical variables, even though their theoretical role in the model is crucial.

The stock adjustment model has been the principal model for analyzing the demand for consumer durables for twenty years. Its use, however, is based on the unjustified assumption that aggregation lets the discrete purchase behavior of individuals be represented as a continuous adjustment process. This paper shows that this approach severely biases the estimated equations. It proposes an alternative model where the implications of infrequent purchase behavior can be explicitly treated.

DATA APPENDIX

Sources: For data listed as taken from the *Survey of Current Business*, data for years prior to 1971 were taken from the 1971 edition of *Business Statistics*, the biennial supplement to the *Surv. Curr. Bus.* Data for 1971 and 1972 were taken from the July 1973 issue of the *Surv. Curr. Bus.*

Total new passenger car retail sales: For 1966–72, *Surv. Curr. Bus.*; prior to 1966, redefined as new passenger car registrations, *Surv. Curr. Bus.*

Disposable income: Surv. Curr. Bus., various issues.

Permanent income: Defined using weights given in M. Friedman, p. 147, plus an estimated time trend. The time trend was introduced because otherwise transitory income was positive for early and late years and negative for middle years.

Transitory income: Defined as real disposable income minus permanent income.

Relative price of new cars: Defined as the ratio of the implicit price deflator for new autos and parts divided by the implicit price deflator for personal consumption expenditures, *Surv. Curr. Bus.* The *BLS* price series for new cars, *Surv. Curr. Bus.*, was also tried and rejected.

Unemployment rate: Surv. Curr. Bus., various issues.

Index of Consumer Sentiment: For 1969–72, data from the 1970–73 annual issues of the *Survey of Consumer Finances*; for years prior to 1969, the revised Index was obtained directly from the Survey Research Center, University of Michigan.

Number of cars in use on January 1 by year of production: For years prior to 1965, data from paper by Charles Friedman; for 1965–69, unpublished data obtained from the Office of Business Economics, U.S. Department of Commerce; for 1970–72, data constructed by extrapolation using scrappage rates given in paper by Franklin Walker.

Strike: Since automobile strikes typically occur near the end of the year and cause postponement of purchases until the beginning of the next year, the strike dummy variable was defined as −1 in 1964, 1967, and 1970 (auto strikes) and in 1959 (steel strike) and as +1 in years following the strike years.

The Deterrent Effect of Capital Punishment: A Question of Life and Death

By ISAAC EHRLICH*

Debate over the justness and efficacy of capital punishment may be almost as old as the death penalty itself. Not surprisingly, and as is generally recognized by contemporary writers on this topic, the philosophical and moral arguments for and against the death penalty have remained remarkably unchanged over time (see Thorsten Sellin (1959, p. 17), and (H. A. Bedau, pp. 120–214). Due in part to its essentially objective nature, one outstanding issue has, however, become the subject of increased attention in recent years and has played a central role in shaping the case against the death penalty. That issue is the deterrent effect of capital punishment, a reexamination of which, in both theory and practice, is the object of this paper.

The multifaceted opposition to capital punishment relies partly upon ethical and aesthetic considerations. It arises also from recognition of the risks of errors of justice inherent in a legal system, errors occasionally aggravated by political, cultural, and personal corruption under certain social regimes. Such errors, of course, are irreversible upon application of this form of punishment. But the question of deterrence is separable from subjective preferences among alternative penal modes and can be studied independently of any such preferences. Of course, the verification or estimation of the magnitude of the deterrent effect of the death penalty—the determination of the expected tradeoff between the execution of a murderer and the lives of potential victims it may help save—can, in turn, influence evaluation of its overall desirability as a social instrument even if that evaluation is largely subjective.

Recent applications of economic theory have presented some analytical considerations and empirical evidence that support the notion that offenders respond to incentives and, in particular, that punishment and law enforcement deter the commission of specific crimes. Curiously, two of the most effective opponents of capital punishment, Beccaria in the 18th century and Sellin in recent years, have never to my knowledge questioned analytically the validity of the deterrent effect of punishment in general. Beccaria even recognizes explicitly the probable existence of such a general effect. What has been questioned by these scholars is the existence of a *differential* deterrent effect of the death penalty over and above its most common practical alternative, life imprisonment (see Beccaria, pp. 115–17). Sellin has presented extensive statistical data that he and others have interpreted to imply, by and large, the absence of such an effect (see Sellin (1959, 1967)).

Whether, in fact, the death penalty constitutes a more severe punishment than life imprisonment for the average potential offender cannot be settled on purely logical grounds, although crime control legislation, ancient and modern, clearly answers this question affirmatively. Observation that convicted offenders almost universally seek and welcome the commutation of a death sentence to life imprisonment is consistent with the intuitive ranking of the death penalty as the harshest of all punishments. Still, one may argue that the differential deterrent effect of capital punishment on the incentive to commit murder may be offset by the added incentive it may create for those who actually commit this crime to eliminate policemen and witnesses who can bring about their apprehension and subsequent conviction and execution.

* University of Chicago and National Bureau of Economic Research. I have benefitted from comments and suggestions from Gary Becker, Harold Demsetz, Lawrence Fisher, John Gould, Richard Posner, George Stigler, and Arnold Zellner. I am particularly indebted to Randall Mark for useful assistance and suggestions and to Walter Vandaele and Dan Galai for helpful computational assistance and suggestions. This paper is a reduced version of a more complete and detailed draft (see the author 1973b). Financial support for this study was provided by a grant to the NBER from the National Science Foundation, but the paper is not an official NBER publication since it has not been reviewed by the board of directors.

The existence of the differential deterrent effect of capital punishment is ultimately an empirical matter. It cannot, however, be studied effectively without thorough consideration of related theoretical issues. The crucial empirical question concerns the kind of statistical test to devise in order to accept or reject the relevant null hypothesis. Since the inquiry concerns a hypothetical deterrent effect, the null hypothesis should be constructed in a form that permits testing of the relevant set of behavioral relations implied by a general theory of deterrence. That includes the deterrent effects of law enforcement activities in general. Moreover, even if a negative effect of capital punishment on the rate of murder is established through systematic empirical research, there still remains the question of the existence of a *pure* deterrent effect distinct from a potential preventive or incapacitating effect associated with this form of punishment. An effect of the second type might be expected since execution eliminates categorically the possibility of recidivism.

Contrary to previous observations, this investigation, although by no means definitive, does indicate the existence of a pure deterrent effect of capital punishment. In fact, the empirical analysis suggests that on the average the tradeoff between the execution of an offender and the lives of potential victims it might have saved was of the order of magnitude of 1 for 8 for the period 1933–67 in the United States. Two related arguments are offered in this context of which only the second will be elaborated in this paper. First, it may be argued that the statistical methods used by Sellin and others to infer the nonexistence of the deterrent effect of capital punishment do not provide an acceptable test of such an effect and consequently do not warrant such inferences. Second, it is argued that the application of the economic approach to criminality and the identification of relevant determinants of murder and their empirical counterparts permit a more systematic test of the existence of a differential deterrent effect of capital punishment. The theoretical approach, emphasizing the interaction between offense and defense—the supply of and the (negative) social demand for murder—is developed in Section I. Section II is devoted to the empirical implementation of the model. Some implications of the empirical evidence are then presented and discussed in Section III.

I. An Economic Approach to Murder and Defense Against Murder

A. *Factors Influencing Acts of Murder and Other Crimes Against Persons*

The basic propositions underlying the approach to murder and other crimes against the person are 1) that these crimes are committed largely as a result of hate, jealousy, and other interpersonal conflicts involving pecuniary and nonpecuniary motives or as a by-product of crimes against property; and 2) that the propensity to perpetrate such crimes is influenced by the prospective gains and losses associated with their commission. The abhorrent, cruel, and occasionally pathological nature of murder notwithstanding, available evidence is at least not inconsistent with these basic propositions. Victimization data reveal that most murders, as well as other crimes against the person, occur within the family or among relatives, friends, and other persons previously known to one another, and are not committed as a rule by strangers on the street (see President's Commission on Law Enforcement and Administration of Justice (*PCL*), pp. 14, 15, 81, and 82). Indeed, hate and other interdependencies in utility across persons as well as malevolent and benevolent exchanges would seem more likely to develop among groups that exercise relatively close and frequent social contact than among groups that exercise little or no contact. There is no reason a priori to expect that persons who hate or love others are less responsive to changes in costs and gains associated with activities they may wish to pursue than persons indifferent toward the well-being of others.

More formally, assume that person o's utility from a consumption prospect C_o, depends upon his own consumption c_o, and consumption activities involving other persons c_j, $j=1, \ldots n$, or

$$(1) \qquad U_o(C_o) = U_o(c_o, c_j)$$

where the sign of $\partial U_o/\partial c_j$ indicates the direction in which o's utility is affected by consumption activities pursued by others. The key feature of this consumption model involving interdependent preferences[1] is that it provides a framework for analyzing positive or negative transfers of resources by one person (here identified with person o) that modify the levels of consumption enjoyed by others while simultaneously determining his own consumption level. Such modifications are constrained generally by the pertinent transfer production functions, by the endowments of resources possessed by person o and other relevant persons, and by potential awards and penalties that are conditional upon o's benevolent or malevolent actions with varying degrees of uncertainty.[2]

This framework can be applied to analysis of the incentive to commit murder and other crimes against the person by explicitly incorporating into the model the uncertainties associated with the prospective punishments for crime. Specifically, murder can be considered a deliberate action intended by an offender o to inflict severe harm on a victim v by setting c_v equal to, say, zero. The offender undergoes some direct costs of planning and executing the crime, and bears the risk of incurring detrimental losses in states of the world involving apprehension, conviction, and punishment.[3] Assuming the offender

---

[1] For a more complete discussion of this model, see Harold Hochman and James Rodgers, and Gary Becker (1974).

[2] It might be argued that although the wish to harm other persons cannot be rejected on economic grounds, nonetheless the execution of such desires (as opposed to benevolent actions) must be considered irrational in the sense of violation of Pareto optimality conditions. If there were no bargaining, transfer, or enforcement costs associated with mutually acceptable and enforceable contracts between a potential offender o and his potential victim v, and if v's wealth constraint were not binding, then it would always be optimal for v to offer compensation to o for not committing a crime against him and for o to seek such compensation or extortion. The reason is that a reduction in v's consumption level is thus achieved by o without incurring the direct costs of committing a crime and the prospective cost of legal sanctions. Indeed, there exists some range of compensations that would increase both o's and v's utilities relative to their expected utilities if crime is committed by o against v. Many crimes against persons, and some cases of property crimes as well, may occasionally be avoided by such arrangements; successful extortions involving kidnapping or hijacking constitute obvious examples. Yet in many situations compensations may be too costly to pursue or to enforce, just as fully effective private or public protection against murder may be too costly to provide. The incidence of murder must then be expected on purely economic grounds.

[3] The case in which crime is committed in pursuit of material gains has been analyzed explicitly by the

TABLE 1

Event		State s	Probabilities π_s	Consumption Prospect C_s
Apprehension	conviction of murder	execution	$(Pa)(Pc\|a)(Pe\|c)$	C_d: $(c_o=0;\ c_v=0)$
		imprisonment for murder	$(Pa)(Pc\|a)(1-Pe\|c)$	C_c: $(c_o=c;\ c_v=0)$
	conviction of a lesser offense or acquittal	other punishment	$Pa(1-Pc\|a)$	C_b: $(c_o=b;\ c_v=0)$
No Apprehension		no punishment	$1-Pa$	C_a: $(c_o=a;\ c_v=0)$

behaves as if to maximize expected utility, a necessary and sufficient condition for murder to occur is that o's expected utility from crime exceeds his expected utility from an alternative (second best) action:

$$(2)\quad U^*_{om}(C^m_o \mid c_v = 0) \equiv \sum_{s=a}^{S} \pi_s U_o(C_{os}) > U^*_{ol}(C^l_o \mid c_v = c^l_v),$$

where $s=a, \ldots, S$ denote a set of mutually exclusive and jointly exhaustive states of the world including all the possible outcomes of murder; c_{os} denote the offender's consumption levels, net of potential punishments and other losses, that are contingent upon these states; π_s denote his subjective evaluation of the probabilities of these states; and C^m_o and C^l_o denote, respectively, his consumption prospect in the event he commits murder or takes an alternative action.

To illustrate the behavioral implications of the model via a simple yet sufficiently general example, assume the existence of just four states of the world associated with the prospect of murder as summarized in Table 1. In Table 1, Pa denotes the probability of the event of apprehension and $1-Pa$ denotes its complement—the probability of escaping apprehension; $Pc|a$ denotes the conditional probability of conviction of murder given apprehension, and $1-Pc|a$ denotes its complement—the probability of conviction of a lesser offense (including acquittal); finally, $Pe|c$ and $1-Pe|c$ denote, respectively, the conditional probabilities of execution and of other punishments given conviction of murder. The (subjective) probabilities of the set of states introduced in Table 1 are equal by definition to the relevant products of conditional probabilities of sequential events that lead to this more final set of states. The last column in Table 1 lists the consumption levels that are contingent upon the occurrence of these states. Economic intuition suggests that the relevant consumption levels can be ranked according to the severity of punishment imposed on the offender; that is, $C_a > C_b > C_c > C_d$.

In the preceding discussion the incidence of murder has been viewed to be motivated by hate. As hinted earlier in the discussion, however, murder could also be a by-product, or more generally, a complement of other crimes against persons and property. Since the set of states of the world underlying the outcomes of these other crimes also includes punishment for murder, the decision to commit these would also be influenced by factors determining the probability distribution of outcomes considered in Table 1. In turn, the incidence of murder would be influ-

---

author (1973a). Note that the victim's level of consumption need not directly enter the offender's utility function in this case.

enced by factors directly responsible for related crimes. In general, behavioral implications concerning the effect of various opportunities on the incidence of murder ought to be analyzed within a framework that includes related crimes as well. For methodological simplicity and because data exigencies rule out a comprehensive empirical implementation of such a framework, the following discussion emphasizes the effect of factors directly related to murder and the direct effect on murder of general economic factors like income and unemployment. In practice, however, the effect of these latter factors on murder may be due largely to their systematic effects on particular crimes against property.

1. *The Effects of Probability and Severity of Punishment*

An immediate implication of the model that is independent of the specific motives and circumstances leading to an act of murder is that an increase in the probability or severity of various punishments for murder decreases, relative to the expected utility from an alternative independent activity, the expected utility from murder or from activities that may result in murder. These implications have been discussed at length elsewhere (see the author (1970, 1973a)) but the somewhat more detailed formulation of the model adopted in this paper makes it possible to derive more specific predictions concerning the relative magnitudes of the deterrent effects of apprehension, conviction, and execution that expose the theory to a sharper empirical test. Specifically, given the ranking of the consumption levels in states of the world involving execution, imprisonment, other punishment, and no punishment for murder, as assumed in the preceding illustration, and given the level of the probabilities of apprehension and the conditional probabilities of conviction and execution, it can be shown that the partial elasticities of the expected utility from crime with respect to these probabilities can be ranked in a descending order as follows:

$$\epsilon_{Pa} > \epsilon_{Pc|a} > \epsilon_{Pe|c} \tag{3}$$

where $\epsilon_P = -\partial \ ln \ U^*/\partial \ ln \ P$ for $P = Pa$, $Pc|a$, $Pe|c$.[4] The interesting implication of condition (3) is that the more general the event leading to the undesirable consequences of crime, the greater the deterrent effect associated with its probability: a 1 percent increase in the (subjective) probability of apprehension Pa, given the values of the conditional probabilities $Pc|a$ and $Pe|c$, reduces the expected utility from murder more than a 1 percent increase in the conditional (subjective) probability of conviction of murder $Pc|a$ (as long as $Pc|a<1$), essentially because an increase in Pa increases the overall, i.e., unconditional, probabilities of three undesirable states of the world: execution, other punishment for murder, and punishment for a lesser offense, whereas an increase in $Pc|a$ raises the unconditional probability of the former two states only. A fortiori, a 1 percent increase in $Pc|a$ is expected to have a greater deterrent effect

---

[4] Differentiating equation (2) with respect to Pa, $Pc|a$, and $Pe|c$, using the contingent outcomes of murder as illustrated in Table 1, it can easily be demonstrated that:

$$\begin{aligned}
\epsilon_{Pa} &= -\frac{\partial U^*_{om}}{\partial Pa}\frac{Pa}{U^*_o} = \frac{1}{U^*_o}\{Pa(1-Pc|a) \\
&\quad \cdot[U(C_a)-U(C_b)] + PaPc|a(1-Pe|c) \\
&\quad \cdot[U(C_a)-U(C_c)] + PaPc|aPe|c \\
&\quad \cdot[U(C_a)-U(C_d)]\} > 0 \\
\epsilon_{Pc|a} &= -\frac{\partial U^*_{om}}{\partial Pc|a}\frac{Pc|a}{U^*_o} = \frac{1}{U^*_o}\{PaPc|a(1-Pe|c) \\
&\quad \cdot[U(C_b)-U(C_c)] + PaPc|aPe|c \\
&\quad \cdot[U(C_b)-U(C_d)]\} > 0 \\
\epsilon_{Pe|c} &= -\frac{\partial U^*_{om}}{\partial Pe|c}\frac{Pe|c}{U^*_o} = \frac{1}{U^*_o}\{PaPc|aPe|c \\
&\quad \cdot[U(C_c)-U(C_d)] > 0
\end{aligned}$$

Clearly, $\epsilon_{Pa} > \epsilon_{Pc|a} > \epsilon_{Pe|c} > 0$.

than a 1 percent increase in $Pe|c$ as long as $Pe|c$ is less than unity. If there exists a positive monotonic relation between an average person's subjective evaluations of Pa, $Pc|a$, and $Pe|c$ and the objective values of these variables, and between an average person's expected utility from crime and the actual crime rate in the population, equation (3) would then amount to a testable theorem regarding the partial elasticities of the murder rate in a given period with respect to objective measures of Pa, $Pc|a$, and $Pe|c$. On the basis of this analysis, it can be predicted that while the execution of guilty murderers deters acts of murder, *ceteris paribus*, the apprehension and conviction of guilty murderers is likely to have an even larger deterrent effect.

Analogous to the effects of the probabilities of various punishments for murder, an increase in the severity of these punishments, their probabilities held constant, is generally expected to decrease the expected utility from murder and so to discourage its commission. Due to lack of space, other implications concerning the effect of severity as well as probability of punishment on the elasticities ϵ_{Pa}, $\epsilon_{Pc|a}$, and $\epsilon_{Pe|c}$ are omitted here. For a more complete analysis, see the author (1973b).

2. *Effects of Employment Opportunities, Income, and Demographic Variables*

The model developed in this section suggests that the incentive to commit murder or other crimes that may result in murder in general would depend on permanent income (or wealth), the relevant opportunities to extract related material gains as well as on direct opportunities for malevolent actions, including the direct costs involved in effecting the production of malevolent transfers. The means for a direct implementation of the effect of these latter opportunities are not readily available (see, however, the discussion in fn. 14). In contrast, variations in legitimate and illegitimate earning and income opportunities may be approximated by movements in the rate of unemployment and of labor force participation, U and L, respectively, and in the level and distribution of permanent income Y_p in the population.

The relevance of the latter set of variables has been discussed in detail elsewhere (see the author (1973a)), particularly in connection with crimes against property, some of which involve murder. However, the level and distribution of income within a community may also exert a direct influence on the incentive to commit murder because of their impact on the individual demand for malevolent actions. In addition, although the decision to commit murder is presumably derived from considerations related to lifetime utility maximization, the timing of murder may be affected by variations in the opportunity cost of time throughout the life cycle, because the typical punishment for murder involves a finite imprisonment term. Thus, to the extent that earning opportunities are imperfectly controlled in an empirical investigation, it may be important to investigate the independent effects of variations in demographic variables, such as the age and racial composition of the population, A and NW, respectively. Controlling for variations in age composition may also be important because of the differential treatment of young offenders under the law.

B. *Defense Against Murder*

1. *Factors Determining Optimal Law Enforcement Activity*

Following the approach used by Becker (1968), I shall attempt to derive implications concerning law enforcement activity against murder on the assumption that law enforcement agencies behave as if they seek to maximize a social welfare function by minimization of the per capita loss from murder. Losses accrue from three main elements: harm to victims net of gains to offenders; the direct costs of law enforcement by police and courts; and the net social costs associated with penalties. The behavior of enforcement agencies is assumed to be in accordance with the general implications of the deterrent theory of law enforcement.

The main elements of the social loss function can be summarized by:

$$L = D(q) + C(q, Pc) + \gamma_1 Pc\, Pe \,|\, c\, qd + \gamma_2 Pc(1 - Pe \,|\, c)qm \tag{4}$$

The term $D(q)$ represents the net social damage resulting from the death of victims and other related losses, where $q \equiv Q/N$ denotes the rate of murder in the population. The term $C(q, Pc)$ represents the total cost of apprehending, indicting, prosecuting, and convicting offenders. The aggregate output of these law enforcement activities can be summarized by the fraction of all murders that are "cleared" by the conviction of their alleged perpetrators (assuming a fixed proportional relation between the number of murders and their perpetrators). This fraction θ may be viewed as an objective indicator of the probability that a perpetrator of murder will be convicted of his crime, $Pc = Pa(Pc \,|\, a)$ with one qualification: since the overall probability of error of justice, π—that of apprehending and convicting an innocent person—is greater than nil, the true probability of conviction $0 < Pc < 1$ will be systematically lower than θ. However, to abstract the analysis from a separate determination of the optimal value of ϵ, it is henceforth assumed that Pc and θ are proportionally related, so that C can be defined as a direct function of Pc.[5] The rate of murder q is introduced as a separate determinant of C because of the argument and evidence that the costs of producing a given value of θ are higher for higher levels of q. The larger is q, the larger the number of suspects that must be apprehended, charged, and convicted in order to achieve a given value of θ. Both D and C are assumed to be monotonically increasing, continuously differentiable, and concave functions in each of their respective arguments.

The third and fourth terms in equation (4) represent the per capita social costs of punishing guilty and innocent convicts through execution and imprisonment (or other penalties), respectively. The variables d and m denote the private costs to victims and their families from execution and imprisonment, and the multipliers γ_1 and γ_2 indicate the presence of additional costs or gains to the rest of society from administering and otherwise bearing the respective penalties of execution and imprisonment that are imposed on guilty and innocent convicts.[6] For methodological convenience, the costs of execution and imprisonment can be combined, and equation (4) can be rewritten as:

---

[5] Pc and θ would be proportionally related if the number of arrests of innocent and guilty persons were proportionally related and if the probability of legal error remained constant as more resources were spent on enforcement activity through arrests and prosecutions. Alternatively, it might be argued that Pc and θ are highly (positively) correlated because of the well-known proposition that at any given level of evidence presented in court in reference to the defendant's guilt or innocence, the probability of legal or type I error, α (that of convicting the innocent), is negatively related to the probability of type II error, β (that of acquitting the guilty). Hence α might be negatively correlated with $Pc \,|\, ch = 1 - \beta$ where $P_c \,|\, ch$ denotes the conditional probability that a guilty offender will be convicted once he is charged. However, the assumption that Pc and θ, or $Pc \,|\, ch$ and α, are mutually dependent is made mainly for methodological convenience without affecting the basic implications of the following analysis. More generally, the direct costs of law enforcement activity C may be specified as a function including Pc and the unconditional probability of legal error ϵ as independent arguments so that optimal values of these probabilities may be determined separately via appropriate expenditures.

[6] More specifically, $\gamma_1 = b_1 + \lambda\beta_1$ and $\gamma_2 = b_2 + \lambda\beta_2$, where λ is a coefficient relating Pc to the fraction of murders cleared by convicting innocent persons π and b and β indicate the respective net social costs from

$$(5) \qquad L = D(q) + C(q, Pc) + \gamma_1 Pcfq$$

where $f = (Pe|c)d + \gamma_2(1 - Pe|c)m/\gamma_1$ is a measure of the average social cost of punishment for murder.

Equation (5) identifies the unconditional probability of conviction Pc, and the expected social cost of punishment f, as the main control variables underlying law enforcement activity. Given the harshness of the method of execution, the length of imprisonment terms, and other factors determining d and m (changes in these factors occur slowly in practice) the magnitude of f is largely a function of the conditional probability of execution $Pe|c$. The values of $0 < Pc < 1$ and $0 < Pe|c < 1$ that locally minimize equation (5) must then satisfy the following pair of equilibrium conditions:

$$(6) \quad \left[D_q + C_q + C_p \frac{1}{q_p} + \gamma_1 Pcf(1 - Ep) \right] q_p = 0$$

$$(7) \qquad [D_q + C_q + \gamma_1 Pcf(1 - Ef)] q_f f_e = 0$$

where

$$Ep \equiv - \frac{\partial Pc}{\partial q} \frac{q}{Pc} \equiv \frac{1}{\varepsilon_{Pc}}$$

$$Ef \equiv - \frac{\partial f}{\partial q} \frac{q}{f} \equiv \frac{1}{\varepsilon_f}$$

$$f_e \equiv \frac{\partial f}{\partial Pe|c} = \left(d - \frac{\gamma_2}{\gamma_1} m \right)$$

and the subscripts p, f, and e associated with the variables C and q denote the partial derivatives of the latter with respect to Pc, f, and $Pe|c$, respectively. The product $\gamma_1 f_e$ indicates the difference between the social costs of execution and imprisonment.

In equation (7) the term $-(D_q + C_q)q_f f_e$ represents part of the marginal revenue from execution: the value of the lives of potential victims saved, and the reduced costs of apprehending and convicting offenders due to the differential deterrent effect of execution on the frequency of murder. The term $\gamma_1 Pcf(1 - Ef)q_f f_e$ represents the net marginal social cost of execution: the value to society of the life of a person executed at a given probability of legal error, plus all the various costs of effecting his execution (including mandatory appeals) net of imprisonment costs thereby "saved." Because in equilibrium, the two must be equated, the optimal value of $Pe|c$ need not be unity—capital punishment may not always be imposed even when it is legal—and would depend on the relative magnitude of the relevant costs and gains. A similar interpretation applies to equation (6).

Inspection of the equilibrium conditions given by equations (6) and (7) reveals a number of interesting implications. First, it may be noted that if an increase in $Pe|c$ unambiguously raises the social cost of punishment for murder, that is, if $\gamma_1 f_e = \gamma_1 d - \gamma_2 m > 0$, then in equilibrium, the deterrent effect associated with capital punishment must be less than unity, or $\varepsilon_{P|e} < \varepsilon_f < 1$.[7] Put differently, executions must only decrease the rate of murders in the population but not the rate of persons executed, for otherwise the marginal cost of execution would be negative and a corner solu-

---

punishing guilty and innocent convicts through execution, denoted by the subscript 1, or imprisonment, denoted by the subscript 2. The conditional probability of execution given conviction is implicitly assumed to be equal for all convicts.

[7] By definition,

$$\varepsilon_{Pe|c} \equiv - (\partial q / \partial Pe|c)(Pe|c/q)$$
$$\equiv \varepsilon_f (\partial f / \partial Pe|c)(Pe|c/f) \equiv \varepsilon_f \varepsilon_{f_e}$$

Clearly,

$$\varepsilon_{f_e} = Pe|c[d - (\gamma_2/\gamma_1)m] / \{(\gamma_2/\gamma_1)m + Pe|c[d - (\gamma_2/\gamma_1)m]\}$$

is lower than unity if $[d - (\gamma_2/\gamma_1)m] > 0$. Under this condition, and the assumption that $\gamma_1 > 0$, $\varepsilon_{Pe|c} < \varepsilon_f < 1$.

tion would be achieved at $Pe|c=1$. However, equation (7) does not have the same implications regarding the value of ε_{Pc}. More specifically, equation (6) shows that the marginal costs of conviction include the marginal costs of apprehending and convicting offenders, in addition to the marginal costs of punishing those convicted. Therefore, the overall marginal revenue from convictions must also be higher than that from executions. Indeed, by combining equations (6) and (7), it can readily be shown that in equilibrium, $\varepsilon_{Pc} > \varepsilon_f > \varepsilon_{Pe|c}$;[8] that is, the deterrent effect associated with Pc must exceed the differential deterrent effect associated with $Pe|c$. This proposition is essentially the same as that derived regarding the response of offenders to changes in Pc and $Pe|c$ (see equation (3)). The compatibility of the implications of optimal offense and defense under the assumption that both offenders and law enforcement agencies regard execution to be more costly than imprisonment insures the stability of equilibrium with respect to both activities. It also provides the basis for a sharp empirical test of the theory.

2. *The Interdependencies Among the Murder Rate and the Probabilities of Conviction and Execution*[9]

Any exogenous factor causing a decrease in the severity of punishment for murder via a decrease in $Pe|c$ can be shown to increase the value of Pc because it tends to decrease the marginal costs of conviction and increase its marginal revenue. More specifically, given the values of d and m, an increase in social aversion toward capital punishment or in the costs of the related due process, measured by γ_1, can be shown to produce a decline in the optimal value of $Pe|c$ and a simultaneous increase in the optimal value of Pc. This analysis is consistent with an argument often made regarding the greater reluctance of courts or juries to convict defendants charged with murder when the risk of their subsequent execution is perceived to be undesirably high. Conviction and execution thus can be considered substitutes in response to changes in the shadow price of each. Indeed, the empirical investigation reveals that at least over the period between 1933 and 1969, in which the estimated annual fraction of convicts executed for murder in the United States, denoted by PXQ_1, fell from roughly 8 percent to nil, the national clearance ratios of reported murders, denoted by P^0a, and the fraction of persons charged with murder who were convicted of murder, denoted by $P^0c|a$, on the whole, moved in an opposite direction. The zero order correlation coefficient between PXQ_1, and P^0a is found to be -0.028, while that between PXQ_1 and $P^0c|a$ is found to be -0.19. (In principle, the product $P^0aP^0c|a$ approximates the value of Pc.) The general implication of this analysis is that the simple correlation between estimates of the murder rate and the conditional probabilities of execution cannot be accepted as an indicator of the true differential deterrent effect of capital punishment, because the simple correlation is likely to confound the offsetting effects of opposite changes in Pc and possibly also in the probability and severity of alternative punishments for murder.

Just as convictions and executions are expected to be substitutes with respect to changes in the shadow cost of each activity, they can be expected to be complementary with respect to changes in the severity of damages from crime, essentially because such changes increase the marginal revenues from both activities. Since an exogenous increase in the rate of murder is expected to increase the marginal social damage D_q, and, indirectly, the marginal costs of apprehension and conviction C_q, it is expected to induce an increase in the optimal values of both Pc and $Pe|c$. This analysis demonstrates the simultaneous relations between offense and defense and suggests that the deterrent effects of conviction and execution must be identified empirically through appropriate simultaneous equation estimation techniques.

---

[8] By like reasoning and some simplifying assumptions, it can also be shown that in equibrium, $\varepsilon_{Pa} > \varepsilon_{Pe|a} > \varepsilon_{Pc|a}$.

[9] Proofs to the theorems discussed in this section can be developed through an appropriate differentiation of equations (6) and (7) with respect to the relevant variables.

II. New Evidence on the Deterrent Effect of Capital Punishment

A. *The Econometric Model*

In the empirical investigation an attempt is made to test the main behavioral implications of the theoretical model. The econometric model of crime and law enforcement activity devised by the author (1973a) is applied to aggregate crime statistics relating to the United States for the period 1933–69. The model treats estimates of the murder rate and the conditional probabilities of apprehension, conviction, and execution as jointly determined by a system of simultaneous equations. Since data limitations rule out an efficient estimation of structural equations relating to law enforcement activities or private defense against murder, the following discussion focusses on a supply-of-murders function actually estimated in this study.

1. *The Murder Supply Function*

It is assumed that the structural equations explaining the endogenous variables of the model are of a Cobb-Douglas variety in the arithmetic means of all the relevant variables. The murder supply function is specified as follows.

$$(8)\quad \left(\frac{Q}{N}\right) = CPa^{\alpha_1}Pc\,|\,a^{\alpha_2}Pe\,|\,c^{\alpha_3}U^{\beta_1}L^{\beta_2}Y_p^{\beta_3}A^{\beta_4}\exp(v_1)$$

where C is a constant term and v_1 is a disturbance term assumed to be subject to a first-order serial correlation. The regression equation thus can be written as:

$$(9)\qquad y_1 = Y_1A_1' + X_1B_1' + v_1$$

where

$$(10)\qquad v_1 = \rho v_{1_{-1}} + e_1$$

The variables y_1, Y_1, and X_1 denote, respectively, the natural logarithms of the dependent variable, other endogenous variables, and all the exogenous variables entering equation (8); ρ denotes the coefficient of serial correlation, and the subscript -1 denotes one-period lagged values of a variable. The coefficient vectors A_1' and B_1' have been estimated jointly with ρ and the standard error of e_1, σ_e, via a nonlinear three-round estimation procedure proposed by Ray Fair.

2. *Variables Used*

The dependent variable of interest (Q/N) is the true rate of capital murders in the population in a given year. The statistic actually used, $(Q/N)^0$, is the number of murders and nonnegligent manslaughters reported by the police per 1,000 civilian population as computed from data reported by the FBI *Uniform Crime Report* (*UCR*)[10] and the Bureau of the Census. This statistic can serve as an efficient estimator of the true Q/N if the two were related by:

$$(11)\qquad \left(\frac{Q}{N}\right) = k\left(\frac{Q}{N}\right)^0 \exp\mu$$

where k indicates the ratio of the true number of capital murders committed in a given year relative to all murders reported to the police, and μ denotes random errors of reporting or identifying murders. It should be noted, however, that the fraction of capital murders among all murders may have been subject to a systematic trend over time. Indeed, the theory developed in Section IA suggests that the decrease in the tendency to apply the death penalty in the United States over time may have led to an increase in the fraction of capital murders among all murders. More important, the number of reported murders may have decreased systematically over time because of the decrease in the fraction of all attempted murders resulting in the death of the victims due to the continuous improvement in medical technology. To account for such possible trends, the term k in equation (11) can be defined as $k=\delta \exp(\lambda T)$, where δ and λ are constant terms and T denotes chronological time. Upon substitution of $(Q/N)^0$ for (Q/N) in equation (8), the inverse values of δ and μ would be subsumed under the constant term C and the stochastic variable v, respectively, and $\exp(-\lambda T)$ would emerge as an additional explanatory variable. Thus, the natural value of T is introduced in equation (9) as an independent exogenous variable.[11]

---

[10] I am indebted to the Uniform Crime Reporting Section of the FBI for making available their revised annual estimates of the total number of murders and other index crimes in the United States during the period 1933–65.

The matrix of endogenous variables associated with Y_1 in equation (9) includes the conditional probabilities that guilty offenders be apprehended, convicted, and executed for murder. These probabilities have been approximated by computing objective measures of the relevant fractions of offenders who are apprehended, convicted, and executed. The following paragraphs contain a brief discussion of these measures.

Pa is measured by the national "clearance rates" as reported by the FBI *UCR*, which are estimates of the percentage of all murders cleared by the arrest of a suspect. It is denoted by P^0a. The conditional probability $Pc|a$ is identically equal to $Pch|a \cdot Pc|ch$—the product of the conditional probabilities that a person who committed murder be charged once arrested, and that he be convicted once charged. Statistical exigencies preclude the estimation of a complete series of $Pch|a$, but $Pc|ch$ is estimated by the fraction of all persons charged with murder who were convicted of murder in a given year as reported by the FBI *UCR*. This fraction, denoted by $P^0c|a$, may serve as an efficient estimator of the overall true probability $Pc|a$, provided that $Pch|a$ were either constant over time, or proportionally related to the probability of arrest Pa.

The actual measures of $Pe|c$ consist of alternative estimates of the expected fractions of persons convicted of murder in a given year who were subsequently executed, $P^0e|c$. Because no complete statistics on the disposition of murder convicts by type of punishment are available, however, $P^0e|c$ has been estimated indirectly by matching annual time-series data on convictions and executions. Over most of the period considered in this investigation (up to 1962), executions appear to lag convictions by 12 to 16 months on the average. An objective measure of $P^0e|c$ in year t, therefore, may be the ratio of the number of persons executed in year t+1 to the number convicted in year t or $PXQ_1=E_{t+1}/C_t$.[12] It must be pointed out, however, that the number of persons executed in year t+1, and hence PXQ_1, is, of course, unknown in year t and must be forecast by potential offenders. Even if expectations with respect to PXQ_1 were unbiased on the average, the actual magnitude of PXQ_1 is likely to deviate randomly from its expected value in year t. The effect of such random noise would be to bias the regression coefficient associated with PXQ_1 toward zero. I have therefore constructed four alternative forecasts of the desired variable: $PXQ_{1_{-1}} = E_t/C_{t-1}$; $PXQ_2 = E_t/C_t$; $TXQ_1 =$ the systematic part of PXQ_1 computed via a linear distributed lag regression of PXQ_1 on three of its consecutively lagged values; and $PDL_1 =$ the systematic part of PXQ_1 computed via a second degree polynomial distributed lag function relating PXQ_1 and four of its consecutively lagged values. The advantage of using these alternative estimates of the expected $P^0e|c$ is that all being based on past data, they may be treated largely as predetermined rather than as endogenous variables. Alternatively, PXQ_1 is treated as an endogenous variable along with P^0a and $P^0c|a$, and its systematic part is computed via the reduced form regression equation (see Table 3).

---

[11] Another important reason for introducing chronological time as an exogenous variable in equation (8) is to account for a possible time trend in missing variables, in particular, the average length of imprisonment for both capital and noncapital murders for which no complete time-series is available. Scattered evidence shows rising trends in the median value of prison terms served by all murder convicts over a large part of the period considered in this investigation, but this increase may have been largely technical. With executions being imposed less frequently over time, the frequency of life imprisonment sentences for murder convicts may have risen accordingly, thus increasing the mean or median time spent in prisons by these convicts.

[12] Execution figures are based on *National Prisons Statistics Bulletin* (*NPS*) statistics. Conviction figures are derived by $C_t=Q_t^0P^0a_tP^0c|a_t$. Statistics on the time elapsed between sentencing and execution can be found in *NPS* numbers 20 and 45.

Two difficulties associated with the use of the proposed estimates of $P^0e|c$ as measures of the true conditional probability of execution warrant special attention. First, it may be argued that the fraction of convicts executed for murder may represent only the fraction of those convicted of *capital* murders among all murder convicts. Variations in PXQ_1 or in other related estimates might then be entirely unrelated to the probability that a convict liable to be punished by the death penalty will be actually executed, and the expected elasticity of the murder rate with respect to these estimates might be nil. However, the significant downward trend in PXQ_1 between 1933 and 1967 suggests, especially during the 1960's, that it may serve as a useful indicator of the relative variations in the true $Pe|c$. Second, it should be noted that the relative variation in the reported national murder rate relates to the United States as a whole, whereas the measures of $P^0e|c$ relate to only a subset of states which retained and actually enforced capital punishment throughout the period considered. Thus, the empirical estimates of the elasticities of the national murder rate with respect to $P^0e|c$ may, on this ground, be expected to understate the true elasticities of the murder rate in retentionist states only.

The matrix of exogenous variables associated with X_1 in equation (9) includes annual census estimates of the labor force participation rate of the civilian population 16 years and over (calculated by excluding the armed forces from the total noninstitutional population) L; the unemployment rate of the civilian labor force U; Milton Friedman's estimate of real per capita permanent income (extended through 1969)[13] Y_p; the percentage of residential population in the age group 14–25, A; and chronological time T. Other exogenous variables assumed to be associated with the complete simultaneous equation model of murder and law enforcement X_2 are one-year lagged estimates of real expenditure on police per capita $XPOL_{-1}$ and annual estimates of real expenditure by local, state, and federal governments per capita $XGOV$. Real expenditures are computed by deflating *Survey of Current Business* estimates of current expenditures by the implicit price deflator for all governments. In addition, X_2 includes the size of the total residential population in the United States N, and the percent of nonwhites in residential population NW. The reason for including NW in the list of variables subsumed under X_2 is discussed below in Section IIB. A list of all the variables used in the regression analysis is given in Table 2.

---

[13] I am indebted to Edi Karni for making available to me his updated calculations of the permanent income variable.

B. *The Empirical Findings*

An interesting finding which poses a challenge to the validity of the analysis in Section I is that over the period 1933–69, the simple correlation between the reported murder rate and estimates of the objective risk of execution given conviction of murder is positive in sign. For example, the simple correlation coefficients between $(Q/N)^0$ and PXQ_1, $PXQ_{1_{-1}}$, and PXQ_2 are found to be 0.140, 0.096, and 0.083, respectively. However, the results change substantively and are found to be in accordance with the theoretical predictions and statistically meaningful when the full econometric framework developed in the preceding section is implemented against the relevant data. Despite the numerous limitations inherent in the empirical counterparts of the desired theoretical constructs, the regression results reported in Tables 3 and 4 uniformly exhibit a significant negative elasticity of the murder rate with respect to each alternative measure of the probability of execution. More importantly, the regression results also corroborate the specific theoretical predictions regarding the effects of apprehension, conviction, unemployment, and labor force participation.

Table 3 shows that the estimated elasticity of the murder rate with respect to the conditional probability of execution is

TABLE 2—VARIABLES USED IN THE REGRESSION ANALYSIS, ANNUAL OBSERVATIONS 1933–69

	Variable	Mean (Natural Logarithms)	Standard Deviation (Natural Logarithms)	Arithmetic Mean
y_1	$(Q/N)^0$ = Crime rate: offenses known per 1,000 civilian population.	−2.857	0.156	0.058
Y_1	P^0a = Probability of arrest: percent of offenses cleared.	4.997	0.038	89.835
	$P^0c\|a$ = Conditional probability of conviction: percent of those charged who were convicted of murder.[a]	3.741	0.175	42.733
	$P^0e\|c$ = Conditional probability of execution; PXQ_1 = the number of executions for murder in the year t+1 as a percent of the total number of convictions in year t.[b]	0.176	1.749	2.590
X_1	L = Labor force participation: fraction of the civilian population in the labor force.	−0.546	0.030	0.579
	U = Unemployment rate: percent of the civilian labor force unemployed.	1.743	0.728	7.532
	A = Fraction of residential population in the age group 14–24.	−1.740	0.118	0.177
	Y_p = Friedman's estimate of (real) permanent income per capita in dollars.	6.868	0.338	1012.35
	T = Chronological time (years): 31–37.	2.685	0.867	19.00
X_2	NW = Fraction of nonwhites in residential population.	−2.212	0.063	0.110
	N = Civilian population in 1,000s.	11.944	0.161	155,853
	$XGOV$ = Per capita (real) expenditures (excluding national defense) of all governments in million dollars.	−7.661	0.501	.000532
	$XPOL_{-1}$ = Per capita (real) expenditures on police in dollars lagged one one year.[a]	2.114	0.306	8.638

[a] The figures for $P^0c|a$ (1933–35) and $XPOL$ (all the odd years 1933–51) were interpolated via an auxiliary regression analysis.

[b] The actual number of executions 1968, 1969, and 1970 was zero. However, the numbers were assumed equal to 1 in each of these years in constructing the value of PXQ_1 in 1967–69.

Note: All variables except T are in natural logarithms. The definitions of these variables are given in Table 2. The term Δ^*X denotes the linear operation $X-\hat{\beta}X_{-1}$. The value of β is estimated via the Cochrane-Orcutt iterative procedure (*CORC*). The term $\hat{\sigma}_e$ is defined in Section IIA1. The terms $\Delta^*\hat{P}a$ and $\Delta^*\hat{P}c|a$ in equations 1–5 are computed via a reduced form regression equation including: *C*(constant), Q/N_{-1}, Pa_{-1}, $Pc|a_{-1}$, $P^oe|c$, *L*, *A*, Y_p, *U*, T, $P^oe|c_{-1}$, L_{-1}, A_{-1}, Y_{p-1}, U_{-1}, $XPOL_1$, *XGOV*, *NW*, *N*. The terms $\Delta^*\hat{P}a$, $\Delta^*\hat{P}c|a$, and $\Delta^*\hat{P}XQ_1$ in equation 6 are computed via the same reduced form with $PXQ_1(P^oe|c)$ excluded.

lowest in absolute magnitude when the objective measure of $Pe|c$, PXQ_1, is treated in the regression analysis as if it were a perfectly forecast and strictly exogenous variable. The algebraic value of the elasticity associated with PXQ_1 is −0.039 with upper and lower 95 percent confidence limits (calculated from the normal distribution) of 0.008 and −0.086. The corresponding elasticities associated with the alternative measures of $Pe|c$, PXQ_{1-1}, PXQ_2, TXQ_1, $\hat{P}XQ_1$, and PDL_1

Note: same references as in Table 3 but the reduced form used to compute $\Delta^*\hat{P}^o a$ and $\Delta^*\hat{P}^o c|a$ does not include *N*.

[a] Same as equations 3 and 4 in Table 3 with the missing data pertaining to $XPOL_{-1}$ interpolated via a smoothing procedure.

[b] Same as equation 4 in Table 3 with $\hat{\rho}$ assumed to be zero (level regression).

vary between -0.049 and -0.068 with upper and lower 90 percent confidence limits ranging between -0.01 and -0.10. These results have been anticipated by the analysis of Section IIA2 where it was suggested that the regression coefficient associated with PXQ_1 is likely to be biased toward zero due to the effect of random forecasting errors. In addition, since the analysis of optimal social defense against murder suggests that an exogenous change in (Q/N) may change the socially optimal value of $Pe|c$ in the same direction, the coefficient associated with PXQ_1 may be biased toward a positive value because of a potentially positive correlation between (Q/N) and the unsystematic part of PXQ_1. This simultaneous equation bias is expected to be eliminated when the systematic part of PXQ_1 is estimated via the reduced form regression equation $(\hat{P}XQ_1)$. It is noteworthy that the estimated elasticities of $(Q/N)^0$ with respect to alternative measures of $Pe|c$ are found generally low in absolute magnitude. This, perhaps, is the principal reason why previous studies into the effect of capital punishment on murder using simple correlation techniques and rough measures of the conditional risk of execution have failed to identify a systematic association between murder and the risk of execution.

The regression results regarding the effects of P^0a, $P^0c|a$, and $P^0e|c$ constitute perhaps the strongest findings of the empirical investigation. Not only do the signs of the elasticities associated with these variables conform to the general theoretical expectations, but their ranking, too, is consistent with the predictions in Section I. Table 3 shows that the elasticities associated with P^0a range between -1.0 and -1.5, whereas the elasticities associated with $P^0c|a$ in the various regression equations range between -0.4 and -0.5. And, as indicated in the preceding paragraph, the elasticities associated with $P^0e|c$ are lowest in absolute magnitude. Consistent with predictions and evidence presented in Section IB regarding a negative association between $P^0e|c$ on the one hand and P^0a and $P^0c|a$ on the other, introduction of the latter variables in the regression equation is found to be particularly useful in isolating the (negative) deterrent impact of estimates of $P^0e|c$. Of similar importance is the introduction of the time trend T.

The estimated values of the elasticities associated with the unemployment rate U, labor force participation L, and permanent income Y_p in Table 3 are not inconsistent with the theoretical expectations discussed in Section IA. Of particular interest is that the effects of equal percentage changes in $P^0e|c$ and U are found to be nearly alike in absolute magnitude. Because murder is often a by-product of crimes involving material gains, the positive effect of U on $(Q/N)^0$ may be attributed in part to the effect of the reduction in legitimate earning opportunities on the incentive to commit such crimes. Indeed, preliminary time-series regression results show that the elasticities of robbery and burglary rates with respect to the unemployment rate are even larger in magnitude than the corresponding elasticities of the murder rate. These results conform more closely to theoretical expectations than do the results in a cross-state regression analysis (see the author (1973a)). The reason, presumably, is that due to their higher correlation with cyclical variations in the demand for labor, changes in U over time measure the variations in both involuntary unemployment and the duration of such unemployment more effectively than do variations in U across states at a given point in time. The estimated negative effect of variations in the labor force participation rate on the murder rate can be explained along similar lines. Theoretically, variations in L are likely to reflect opposing income and substitution effects of changes in market earning opportunities. However, with measures of both permanent income Y_p, and the rate of unemployment introduced in the regression equation as independent explanatory variables, changes in L may reflect a pure substitution effect of changes in legitimate earning opportunities on the incentive to commit crimes both against persons and property.[14] Finally, the positive association between Y_p and $(Q/N)^0$ need not imply a positive income elasticity of demand for hate and malice since changes in the *level* of the personal distribution of income may be strongly correlated with payoffs on crimes against property. If legitimate employment opportunities are effectively accounted for by U and by L, changes in Y_p may be highly correlated with similar changes in the incidence of crimes against property. Such a partial correlation is indeed observed across states and in a time-series regression analysis of crimes against property now in progress.

The positive effect of variations in the percentage of the population in the age group 15–24, A, on the murder rate is consistent with the cross-state evidence concerning the correlation between these variables. A possible explanation for this finding was already offered in Section IIA2. Additional analysis, not reported herein, indicated that the effect of the percentage of nonwhites in the population NW becomes statistically insignificant when the time trend T is introduced as an independent explanatory variable in the regression equation. Consequently, this variable is excluded from the regressions estimating the supply of murders function. This result stands in sharp contrast to the ostensibly positive effect of NW on the murder rate across states. I have argued elsewhere in this context that the apparently higher participation rate of nonwhites in all criminal activities may result largely from the relatively poor legitimate employment opportunities available to them (see the author (1973a)). Since, over time, variations in these opportunities may be effectively accounted for by the variations in U and L, the estimated independent effect of NW may indeed be nil. The negative partial effect of T on $(Q/N)^0$ reported in Tables 3 and 4 is not inconsistent with the predictions advanced in Section IIA2.

The regression results are found to be robust with respect to the functional form of the regression equation. In addition, estimating the regression equations by introducing the levels of the relevant variables rather than their modified first differences (that is, assuming no serial correlation in the error terms) artificially reduces the standard errors of the regression coefficients as would be expected on purely statistical grounds (see Table 4, equation (3)). The results are further insensitive as to the specific estimates of expenditures on police used in the reduced form regression equation. The data for this variable are not available for all the odd years between 1933 and 1951 and the missing statistics were interpolated either via a reduced form regression analysis (*XPOL*) or a simple smoothing procedure. The results are virtually identical (compare equations (1) and (2) in Table 4 with equations (3) and (4) in Table 3). The introduction of a dummy variable distinguishing the World War II years (1942–45) from other years in the sample has no discernible effect on the regression results, while the effect of the dummy variable itself appears to be statistically insignificant.

---

[14] A possible explanation for the significant negative association between labor force participation and particularly crimes against the person is that interpersonal frictions and social interactions leading to acts of malice occur mostly in the nonmarket or home sector rather than at work. An increase in the total time spent in the nonmarket sector (a reduction in L) might then generate a positive scale effect on the incidence of murder. This *ad hoc* hypothesis is nevertheless supported by FBI *UCR* evidence on the seasonal pattern of murder. This crime rate peaks twice a year: around the holiday season (December) and around the summer vacation season (July–August) in which relatively more time is spent out of work. It is also supported by evidence that the frequency of murders on weekends is significantly higher than on weekdays (see William Graves, p. 327).

Of more importance, the qualitative results reported in Table 3 are for the most part insensitive to changes in the specific interval of time investigated in the regression analysis, as indicated by the results reported in Table 4. However, the absolute magnitudes of some of the estimated elasticities, especially those associated with P^0a, $P^0c|a$, $P^0e|c$, U, and L do change when estimated from different subperiods. Finally, the time-series estimates of the supply-of-murders function appear quite consistent with independent estimates derived through a cross-state regression analysis using data from 1960. A detailed discussion of related issues is included in the author (1973b).

III. Some Implications

A. *The Apparent Effect of Capital Punishment: Deterrence or Incapacitation?*

It has already been hinted in the introduction to this paper that an apparent negative effect of execution on the murder rate may merely reflect the relative preventive or incapacitating impact of the death penalty which eliminates the possibility of recidivism on the part of those executed. An estimation of the differential preventive effect of execution relative to imprisonment for capital murder has been attempted in this study through an application of a general model of the preventive effect of imprisonment developed in the author (1973a). In this application of the model, execution is identified with an imprisonment term Te, which is equal to the life expectancy of an average offender imprisoned for murder. The differential preventive impact of execution is estimated by taking account of the alternative average sentence served by those imprisoned for capital murder Tm, the fractions of potential murders executed and imprisoned, and the rate of population growth.

Derivation of the expected partial elasticity of the murder rate with respect to the fraction of convicts executed, $\sigma_{P^0e|c}$, is omitted here for lack of space. I shall point out only that estimates of $\sigma_{P^0e|c}$ derived on the basis of the extremely unrealistic assumption that any potential murderer at large (outside prison) commits one murder each and every year and for values of Te and Tm estimated at 40, and between 10 and 16 years, respectively, vary between 0.020 and 0.037 (see the author (1973b)). These estimates, therefore, do not account for the full magnitudes of the absolute values of the elasticities of the murder rate with respect to estimates of the fraction of convicts executed that are reported in Tables 3 and 4. Moreover, according to the model of law enforcement involving only preventive effects, the partial elasticity of the murder rate with respect to the fraction of those apprehended for muder P^0a is expected to be identical to the corresponding elasticity with respect to the fraction of those apprehended and charged with murder who were convicted of this crime, $P^0c|a$. The reason, essentially, is that equal percentage changes in either P^0a or $P^0c|a$ have the same effect on the fractions of offenders who are incapacitated through incarceration or execution, and thus should have virtually equivalent preventive effects on the murder rate. This prediction is ostensibly at odds with the significant positive difference between empirical estimates of the murder rate with respect to P^0a and $P^0c|a$. In contrast, the latter findings are consistent with implications of the deterrent theory of law enforcement (see equation (3)). In light of these observations one cannot reject the hypothesis that punishment in general, and execution in particular, exert a unique deterrent effect on potential murderers.

B. *Tentative Estimates of the Tradeoff Between Executions and Murders*

The regression results concerning the partial elasticities of the reported murder rate with respect to various measures of the expected risk of execution given conviction in different subperiods $\hat{\alpha}_3$, can be restated in terms of expected tradeoffs between the execution of an offender and the lives of potential victims that might thereby be saved. For illustration, consider the regression coefficients associated with $\hat{P}XQ_1$ and $PXQ_{1_{-1}}$ in equations (6) and (3) of Table 3. These coefficients, -0.06 and -0.065, respectively, may be considered consistent estimates of the average elasticity of the national murder rate, $(Q/N)^0$, with respect to the objective conditional risk of execution, $P^0e|c=(E/C)^0$, over the period 1935–69. Evaluated at the mean values of murders and executions over that period, $\bar{Q}=8{,}965$ and $\bar{E}=75$, the marginal tradeoffs, $\Delta Q/\Delta E=\hat{\alpha}_3\bar{Q}/\bar{E}$, are found to be 7 and 8, respectively. Put differently, an additional execution per year over the period in question may have resulted, on average, in 7 or 8 fewer murders. The weakness inherent in these predicted magnitudes is that they may be subject to relatively large prediction errors. More reliable point estimates of the expected tradeoffs should be computed at the mean values of all the explanatory variables entering the regression equation (hence, also the mean value of the dependent variable) because the confidence interval of the predicted value of the dependent variable is there minimized. The mean values of the dependent variable and the explanatory variable used to calculate the value of $\hat{\alpha}_3$ in equation (3) of Table 3 are found to be nearly identical with the actual values of these two variables in 1966 and 1959, respectively. The corresponding values of murders and executions in these two years were $Q(1966)=10{,}920$ and $E(1959)=41$; the marginal tradeoffs between executions and murders based on the latter magnitudes and the elasticity $\hat{\alpha}_3=-0.065$ are found to be 1 to 17.

It should be emphasized that the expected tradeoffs computed in the preceding illustration mainly serve a methodological purpose since their validity is conditional upon that of the entire set of assumptions underlying the econometric investigation. In addition, it should be pointed out that the 90 percent confidence intervals of the elasticities used in the preceding illustrations vary approximately between 0 and -0.10 implying that the corresponding confidence intervals of the expected tradeoffs in the last illustration range between limits of 0 and 24. As the above illustrations indicate, however, although the estimated elasticities $\hat{\alpha}_3$ reported in Tables 3 and 4 are low in absolute magnitude, the tradeoffs between executions and murders implied by these elasticities are not negligible, especially when evaluated at relatively low levels of executions and relatively high levels of murder.[15]

Finally, it should be emphasized that the tradeoffs discussed in the preceding illustrations were based upon the partial elasticity of $(Q/N)^0$ with respect to measures of $P^0e|c$ and thus, implicitly, on the assumption that the values of all other variables affecting the murder rate are held constant as the probability of execution varies. In practice, however, the values of the endogenous variables Pa and $Pc|a$ may not be perfectly controllable. The theoretical analysis in Section IB suggests that exogenous shifts in the optimal values of $Pe|c$ may generate offsetting changes in the optimal values of Pa and $Pc|a$. Indeed, consistent estimates of the elasticities of the reported murder rates with respect to alternative measures of $P^0e|c$ that were derived through a reduced form regression analysis using as explanatory variables only the exogenous and predetermined variables included in the supply of offenses function and other structural equations (X_1 and X_2 in Table 2) are found to be generally lower than the elasticities reported in Table 3.[16] The actual tradeoffs between executions and murders thus depend partly upon the ability of law enforcement agencies to control simultaneously the values of all the parameters characterizing law enforcement activity.

---

[15] A decrease in the number of executions in 1960 from 44 to 2 (the actual number of executions in 1967), which implies a decline of 95 percent in the value of $Pe|c$ in that year, would have increased the murder rate that same year by about 6.2 percent from 0.05 to 0.053 per 1,000 population if the true value of α_3 were equal to 0.065. The implied increase in the actual number of murders in 1960 would have been from 9,000 to 9,558. For comparison, note that the actual murder rate in 1967 was 0.06 per 1,000 population and the number of murders was 12,100. The values of other explanatory variables associated with the supply of murders function were, of course, quite different in these two years. By this tentative and rough calculation, the decline in $Pe|c$ alone might have accounted for about 25 percent of the increase in the murder rate between 1960 and 1967.

IV. Conclusions

This paper has attempted to present a systematic analysis of the relation between capital punishment and the crime of murder. The analysis rests on the presumption that offenders respond to incentives. Not all those who commit murder may respond to incentives. But for the theory to be useful in explaining aggregate behavior, it is sufficient that at least some so behave.

Previous investigations, notably those by Sellin, have developed evidence used to unequivocally deny the existence of any deterrent or preventive effects of capital punishment. This evidence stems by and large from what amounts to informal tests of the sign of the simple correlation between the legal status of the death penalty and the murder rate across states and over time in a few states. Studies performing these tests have not considered systematically the actual enforcement of the death penalty, which may be a far more important factor affecting offenders' behavior than the legal status of the penalty. Moreover, these studies have generally ignored other parameters characterizing law enforcement activity against murder, such as the probability of apprehension and the conditional probability of conviction, which appear to be systematically related to the probability of punishment by execution. In addition, the direction of the causal relationship between the rate of murder and the probabilities of apprehension, conviction, and execution is not obvious, since a high murder rate may generate an upward adjustment in the levels of these probabilities in accordance with optimal law enforcement. Thus the sign of the simple correlation between the murder rate and the legal status, or even the effective use of capital punishment, cannot provide conclusive evidence for or against the existence of a deterrent effect.

The basic strategy I have attempted to follow in formulating an adequate analytic procedure has been to develop a simple economic model of murder and defense against murder, to derive on the basis of this model a set of specific behavioral implications that could be tested against available data, and, accordingly, to test those implications statistically. The theoretical analysis provided sharp predictions concerning the signs and the relative magnitudes of the elasticities of the murder rate with respect to the probability of apprehension and the conditional probabilities of conviction and execution for murder. It suggested also the existence of a systematic relation between employment and earning opportunities and the frequency of murder and other related crimes. Although in principle the negative effect of capital punishment on the incentive to commit murder may be partly offset, for example, by an added incentive to eliminate witnesses, the results of the empirical investigation are not inconsistent with the hypothesis that, on balance, capital punishment reduces the murder rate. But even more significant is the finding that the ranking of the elasticities of the murder rate with respect to Pa, $Pc|a$, and $Pe|c$ conforms to the specific theoretical predictions. The murder rate is also found negatively related to the labor force participation rate and positively to the rate of unemployment. None of these results is compatible with a hypothesis that offenders do not respond to incentives. In particular, the results concerning the effects of the estimates of the probabilities of apprehension, conviction, and execution are not consistent with the hypothesis that execution or imprisonment decrease the rate of murder only by incapacitating or preventing apprehended offenders from committing further crimes.

---

[16] The elasticities associated with PXQ_1, $PXQ_{1_{-1}}$, TXQ_1, and PDL_1 in this modified reduced form regression analysis relating to the period 1934–69 are found equal to −0.0269 (−0.83), −0.0672 (−2.29), −0.0414 (−1.99), and −0.052 (−5.81), respectively, where the numbers in parentheses are the ratios of the coefficients to their standard errors.

These observations do not imply that the empirical investigation has proved the existence of the deterrent or preventive effect of capital punishment. The results may be biased by the absence of data on the severity of alternative punishments for murder, by the use of national rather than state statistics, and by other imperfections. At the same time it is not obvious whether the net effect of all these shortcomings necessarily exaggerates the regression results in favor of the theorized results. In view of the new evidence presented here, one cannot reject the hypothesis that law enforcement activities in general and executions in particular do exert a deterrent effect on acts of murder. Strong inferences to the contrary drawn from earlier investigations appear to have been premature.

Even if one accepts the results concerning the partial effect of the conditional probability of execution on the murder rate as valid, these results do not imply that capital punishment is necessarily a desirable form of punishment. Specifically, whether the current level of application of capital punishment is optimal cannot be determined independently of the question of whether the levels of alternative punishments for murder are optimal. For example, one could argue on the basis of the model developed in Section IA that if the severity of punishments by means other than execution had been greater in recent years, the apparent elasticity of the murder rate with respect to the conditional probability of punishment by execution would have been lower, thereby making capital punishment ostensibly less efficient in deterring or preventing murders. Again, this observation need not imply that the effective period of incarceration imposed on convicted capital offenders should be raised. Given the validity of the analysis pursued above, incarceration or execution are not exhaustive alternatives for effectively defending against murders.[17] Indeed, these conventional punishments may be considered imperfect means of deterrence relative to monetary fines and other related compensations because the high "price" they exact from convicted offenders is not transferrable to the rest of society. Moreover, the results of the empirical investigation indicate that the rate of murder and other related crimes may also be reduced through increased employment and earning opportunities. The range of effective methods for defense against murder thus extends beyond conventional means of law enforcement and crime prevention. There is no unambiguous method for determining whether capital punishment should be utilized as a legal means of punishment without considering at the same time the optimal values of all other choice variables that can affect the level of capital crimes.

---

[17] Ironically, the argument that capital punishment should be abolished because it has no deterrent effect on offenders might serve to justify the use of capital punishment as an ultimate means of prevention of crime, since the risk of recidivism that cannot be deterred by the threat of punishment is not eliminated entirely even inside prison walls. In contrast, since the results of this investigation support the notion that execution exerts a pure deterrent effect on offenders, they can be used to suggest that other punishments, even those which do not have any preventive effect, can in principle serve as substitutes.

China as a Less Developed Economy

By Lloyd G. Reynolds*

The body of development theory which has grown up over the past generation assumes private ownership in both agriculture and industry. The public sector is omitted or assigned only a limited role in the economy. This is true, for example, of the well-known models of John Fei and Gustav Ranis, Dale Jorgenson, Shigeru Ishikawa (1967), and Allen Kelley, Jeffrey Williamson, and Russell Cheatham. There is as yet no theory of socialist development from a low income level.

This note makes no effort to construct such a theory. It has the modest purpose of underlining some aspects of China's development strategy which may be suggestive for model builders. The discussion relates mainly to Chinese experience since 1958. Up to that point Chinese development, which was strongly Soviet influenced as well as Soviet aided, showed the usual socialist emphasis on rapid industialization and a predominant allocation of investment resources to heavy industry. This phase is well documented in the studies by Alexander Eckstein, Walter Galenson, and Ta-Chung Liu, and by Nai-Ruenn Chen and Galenson.

From the "great leap" program initiated in the winter of 1957–58, and from the Chinese-Soviet rift which followed soon thereafter, there ensued a sequence of institutional changes and policy shifts which is still continuing. But while the economy has in no sense come to rest, and while statistical estimates from 1958 onward are conjectural, one can discern the outlines of a development strategy distinctly different from the Soviet pattern, and different also from that of other large, densely populated Asian countries such as India, Indonesia, and Pakistan.

I. The Planners' Objective Function

The development literature of the 1950's and 1960's tended to assume that development consisted in a more rapid growth of *GNP* per capita. But it gradually became apparent that even in countries where output growth was satisfactory, employment growth was considerably slower. The backlog of surplus labor was not being reduced or was even increasing. In many cases, too, additional output was distributed so as to accentuate preexisting inequalities of income. The recent tendency, therefore, has been to downgrade *GNP* increase alone as a success indicator, and to erect instead a trinity of objectives: full employment, a high growth rate of *GNP* per capita, and a more equitable distribution of income.

The objectives of Chinese leaders are in line with this current thinking—indeed, the Chinese were there first. Full mobilization of manpower (and, importantly, of womanpower) was an objective from the beginning, and had been largely accomplished by the early 1950's. The Chinese leadership has also pursued an incomes policy aimed at 1) elimination of poverty, in the sense of establishing a minimum standard of living to which every citizen is entitled; and 2) gradual reduction of income inequalities above the minimum, by methods which will be noted below.

Thus far the three objectives do not

---

* Yale University. Some of the observations in this note stem from a recent visit to China with four economist colleagues, which included extended discussions with Chinese economists and management officials. I have had access also to a number of other travel reports, in addition to published English language sources on the Chinese economy.

seem to have been seriously in conflict. The additional employment which has been created, most of which is necessarily in the countryside, has had a positive marginal product and has thus aided the growth of output. Income equalization has not been pushed to the point where it interferes seriously with work incentives. On the contrary, the fact that many who previously suffered from disease and malnutrition are now healthier and better fed must have increased productive capacity as well as welfare.

In addition to economic objectives whose accomplishment is measurable in principle, several less tangible objectives have an important influence on economic decisions. These objectives, which have been described by John Gurley, Joan Robinson, and others, include:

(i) *Deemphasis of material incentives.* Enterprise managers are paid little more than skilled workers. Profits go entirely to the state, with no bonuses to workers or managers for superior performance. The object is to establish a motivational system in which people will work effectively from social conscience, reinforced by group pressure from fellow workers, rather than for monetary rewards.

(ii) *Antibureaucratization.* In any industrial society, capitalist or socialist, there is a tendency for government officials, industrial managers, and professional experts to crystallize into an élite—Djilas' "ruling class," or Galbraith's "technostructure." Chinese leaders are determined to maintain social fluidity to prevent the emergence of marked distinctions, either of prestige or income. This underlies, for example, the new policy of requiring high school graduates to work for at least two years before they can be considered for university admission, and of giving preference in admission to children of workers and farmers. This is intended to prevent hereditary transmission of status through the educational system.

(iii) *Mass participation in decision making.* This is evidenced in worker membership in the "Revolutionary Committees" which now govern all organizations in China; in the rapid promotion of factory workers to leadership positions during and since the Cultural Revolution; in the establishment of "three-in-one teams," including managers, technicians, and workers, as the responsible groups for industrial research and development. The opposite side of the coin is the downgrading of the expert, the specialist, the technician, who is urged to "learn from the workers," and to spend frequent periods of time in manual labor.

These cardinal points of Maoist doctrine raise difficult questions, to which there are presently no clear answers. How widely are they pursued as well as advocated? Are they feasible objectives over an extended period of time? To what extent does pursuit of these objectives conflict with efficient occupational division of labor, scientific and technical progress, and increase of productivity? Chinese leaders would probably deny the existence of any such conflict. But even if they were persuaded that a tradeoff exists, they would doubtless accept some slowdown of material progress as a reasonable price for better performance in social organization and human relations.

We turn now to China's treatment of several problems which are endemic in the *LDC*s, and particularly in the densely populated countries of South and East Asia: increasing the rate of capital accumulation; producing and transferring adequate food supplies for the urban population; reducing the rate of population growth; preventing premature migration to the cities and the associated rise of urban unemployment; providing adequate employment opportunities in the countryside; and coping with the tendency toward growing income inequality which often marks the early decades of modern economic growth.

II. Devices for Capital Accumulation

While capital is not the sole requisite for growth as it seemed in some early development models, it remains an important requirement. In the older industrial countries, gross capital formation as a percentage of *GNP* rose gradually during the early decades of accelerated growth; and the more successful *LDC*s today are repeating this experience.

The unusual feature of the Chinese case is the suddenness with which the capital formation rate was raised from a low plateau to a much higher plateau. Kung-Chia Yeh, in his contribution to the Eckstein, Galenson, and Liu volume, estimates that the ratio of gross domestic capital formation to *GNP*, measured in constant 1952 prices, averaged 7.4 percent from 1931–36 and 24.0 percent from 1952–57. Shigeru Ishikawa's (1965) estimates for the 1950's are also in the 20–25 percent range.

A major factor in this early period was the redistribution of income associated with the land reform of 1949–52. A substantial share of national income, variously estimated at 15 to 30 percent, had previously gone to landlords, rich gentry, money-lenders, merchants, and others. Land reform redistributed this income, on the first round, among the peasant population. Government then intervened, through tax and price instruments, to capture much of this income and redirect it toward capital formation. There is a parallel here with Japanese government strategy in the early Meiji period, when diversion of income from the previous landed nobility into government channels helped to raise the national savings rate.

While comparable data are not available for more recent years, it seems unlikely that the capital formation rate today is *lower* than in 1952–57. Dwight Perkins estimates that from 1957 to 1972 output of producers' goods rose at an average annual rate of 10 percent per year, compared with 8 percent for all industrial output; and that the share of producers' goods in *GNP* was twice as high in 1972 as in 1957. Granted that part of this increased output went for military purposes, and that the output of heavy industry does not measure construction and other parts of capital formation, the data suggest a continued high capital formation rate.

Within the limits of consumer tolerance, a socialist economy can determine the capital formation rate through control of financial flows as well as through physical resource allocation. There is a price-cost margin for manufactured goods, the allocation of which between taxes and profits is a matter of discretion. In Chinese practice, as distinct from Soviet practice, excise taxes are relatively low and profits correspondingly high; and all profit is remitted to government rather than being shared with the enterprise (though enterprise control over depreciation allowances doubtless permits some net investment under the guise of reinvestment). The price-cost margin varies with the product, being low for agricultural inputs, machinery, and essential consumer goods, and higher for less essential consumer items. Thus, although China has no income tax, there is an element of progressive income taxation in the pricing system.

Another distinctive feature of the Chinese system is the relatively great importance of lower levels of government. The great bulk of industrial activity, and all agricultural activity, is directed by the provinces, counties, and communes. The provinces are accordingly the key revenue-collecting agency. Only about 20 percent of central government revenue is collected directly from national industries and other sources. The remainder comes through transfers from the provinces, which are varied according to the province's ability to pay. This might be termed "revenue sharing from below." Major investment schemes are included in the central government budget, but the bulk of investment is planned and financed via provincial and county budgets.

Much investment, indeed, is carried out at the lowest level of the rural commune. Each production team contributes 3 to 5 percent of its gross income to an "accumulation fund," which finances equipment purchases and other agricultural improvements by the team. The production brigade and the commune draw revenue from machinery leases and other services to the production teams, and also from the profits of their industrial activities. The profits of rural industrial enterprises, unlike the profits of urban industries, are not remitted to the state. The funds remain in the commune and are available for expansion of industrial activities or for agricultural investment. Commune officials report that their present scale of industrial production has been built up largely from reinvested earnings rather than through investment allocations from the state.

III. Generating an Agricultural Surplus

In socialist economies agriculture is typically a lagging sector. It is not clear to what extent this is due to inherent inefficiency of collective or state farming compared with the private "family farm," and how far it stems from antiagriculture bias on the part of policy makers, reflected in underinvestment in agriculture and in pricing and procurement policies which provide little incentive for output increases.

Chinese economic policy has been distinctly more favorable to agriculture than has traditional Soviet policy. Agriculture was not tightly squeezed even during the industrialization drive of the 1950's. While investment allocations to agriculture from the state budget appear small, much of agriculture's saving was left for reinvestment within that sector. The drop in agricultural output during the "great leap" campaign stimulated even greater attention to agricultural output from 1960 onwards.

Much effort has been put into irrigation, pumping, and other water-control systems, permitting both an increase in multiple cropping and heavier fertilizer applications. Production of fertilizer and farm machinery has risen rapidly in percentage terms, though from a low base. Use of modern inputs is encouraged by pricing them close to cost of production. Government procurement prices for grain and other major crops have been raised moderately since 1960, while prices of manufactures have tended downward, so that agriculture's terms of trade have been improving. Agricultural taxation is moderate, taking currently about 6 percent of gross agricultural output. This percentage has declined over time because assessments, which are based on "normal yields," lag behind the increase in output capacity. For non-key products (vegetables, fruits, poultry, eggs, pigs, milk, forestry products, fish), the communes have a high degree of autonomy. Delivery contracts are made directly with municipal trading authorities in nearby cities, at locally negotiated prices.

This package of incentives has stimulated a considerable increase in farm output. Perkins estimates that over the period 1957–72, agricultural output rose at an average annual rate of 3 percent. With population growing at something like 2 percent,[1] this provides a modest margin for dietary improvement.

The 80 percent of the people living in the countryside have to feed the 20 percent in towns and cities. This food transfer occurs in four main ways: (a) the agricultural tax, which is usually paid in grain; (b) quota sales of grain, cotton, sugar, and other key crops to the state procurement organization, at a uniform national price. Quotas appear to be determined as follows: each production team estimates its next year's production of the crop in question, based on an average of recent years. It then (in the case of grain) deducts the basic grain ration for the population of the team. The remainder is the amount which it can undertake to sell. (c) Above-quota sales, which are always permissible if the crop year is unusually good or if there has been a misjudgment of production capacity. For grain, though not for cotton and other cash crops, above-quota sales command a 30 percent price premium. (d) The direct commune-city contracts already mentioned govern most transfers of fruits, vegetables, and livestock products.

Ability to produce and transfer sufficient grain to the cities has enabled the city price of food grains to remain unchanged since the early 1950's. This fact, plus similar stability in the price of cloth and other necessities, removes upward pressure on the wage structure. There have been wage increases, particularly for the lowest paid workers, but these increases have been moderate and entirely discretionary. Wage stability combined with productivity improvement means that unit production costs of manufactured goods are typically falling over time, ensuring profit margins which contribute to capital accumulation and which also permit occasional price reductions, especially for the still relatively expensive consumer durables (bicycles, radios, watches, sewing machines).

The wage-price stability which is one of the unusual features of the Chinese economy thus rests essentially on the price of grain. The importance of preventing any upward pressure on this key price is doubtless one reason, though by no means the only reason, for maintenance of the rationing system despite apparently adequate grain supplies.

If domestic food supplies are adequate, why is China still importing substantial amounts of grain? One can only surmise. It is said that grain inventories are being increased, partly for defense reasons, at all levels from the farm household to the central government. Further, China is a very large country, with food-surplus and food-deficit provinces, and a limited transportation system. It may be efficient to supplement supplies in some of the coastal areas through imports rather than internal shipments. The imports also give China more elbowroom to export food to other less developed countries in the interest of political relations.

While the Chinese are keeping their heads above water on the crucial food front, serious problems remain in the agricultural sector. A central problem is how to generate and disseminate improved agricultural technology. The soil- and climate-specific characteristics of agricultural production make technology transfer from advanced economies more difficult than in industry. Much research and experimentation is usually required to adapt imported seed strains and cultivation methods to local conditions, as well as to generate indigenous improvements. China has a small supply of agricultural scientists. Nor is the present political climate—suspicion of intellectuals, downgrading of professional expertise and specialization, disorganization of the university system—conducive to enlargement of this supply.

---

[1] Neither the size of the population nor its rate of increase is known with any precision. Estimates for the 1950's, reported in Eckstein, Galenson, and Liu, are in the neighborhood of 2 percent. But today's rate of natural increase may be somewhat lower because of intensified efforts at family planning.

A second problem is how the small supply of improved seeds, chemical fertilizer, and other modern inputs should be allocated. Heavy allocations to farm areas which are already relatively productive might do most to raise national output; but it would also widen the income gap between more and less productive farms. On the other hand, allocations to the low-income farms on equity grounds might fail to maximize total output. Little is known about the direction of allocations at present. At any event, the dilemma remains.

IV. Restraining Population Growth

Population increase is the other side of the food problem. Crudely, reducing the population growth rate by 1 percent is as helpful as raising the growth of agricultural output by 1 percent, and in principle is much less expensive. Here China starts with several advantages over most other *LDC*s: an unambiguous commitment to population control by the political leadership; a system of primary education which is already universal in the cities and rapidly becoming so in the countryside; a widespread network of medical clinics and dispensaries, staffed largely by paramedical personnel to complement the small corps of fully trained doctors; and strong social discipline which is perhaps traditionally Chinese, but which is now reinforced by neighborhood associations and Communist Party units.

The most important single device is late marriage. Women are strongly urged not to marry before 25, and men not before 30. After marriage, the two-child family is held up as ideal. Contraceptive information and supplies are available without charge at the dispensaries. Carl Djerassi estimates that about half the urban women of reproductive age use oral contraceptives, and that the 1972 production rate was sufficient to supply 20 million women per year. After a couple has had two children, they are reportedly urged by the neighborhood association to stop at that point. The fact that women are encouraged to work equally with men, and that jobs are always available, provides an additional incentive to family planning. It is obviously easier for a woman to hold a full-time job with two children than with six.

Aggregative data on fertility rates are not available. But one can do amateur demography by inquiring into such things as school enrollments in each primary grade in a commune, or number of babies born in recent years in a housing development of known population. There is good reason to think that city birth rates are falling quite rapidly. Progress in the countryside has admittedly been slower; but the effort is continuing, and the announced objective of reducing the population growth rate to 1 percent (that is, to "developed country" levels) by 2000 A.D. does not seem unrealistic.

V. The Level of Employment

In China, as elsewhere, there are strong incentives to exchange farm work for urban employment. Work in the city is lighter, earnings are higher, educational and cultural amenities are greater. In most *LDC*s the result has been cityward migration in excess of urban labor requirements, a rise in unemployment, growth of "shanty towns" on the edge of the city, increased congestion and pressure on municipal services, and frequently political unrest and violence.

The Chinese use several policy instruments to avert these developments. Perhaps most important is industrial location policy. The announced objective is that the major eastern cities should not increase in size. In general, no new industry will be located in these cities, and there is strong effort to resist employment increases in older industries. New industries in the eastern provinces are located in suburban areas well away from the city center, and with their own housing and shopping facilities. In addition, more than half of industrial investment is now being directed toward the middle and far western provinces.

Other policy instruments include: 1) control of hiring. Enterprises may not recruit workers directly, but must apply to a municipal employment bureau. If an enterprise asks for additional labor, the first response is to urge it to get more output from its present labor force. Second, the bureau tries to make sure that the potential labor supply from the existing urban population is being fully utilized. Only as a last resort will new workers be accepted from the countryside. 2) Control of housing allocations. A would-be migrant from the country who applies for an apartment in the city is asked, "Do you have a job?" If the answer is no, he is back to square one. 3) The food and clothing rationing system. Every citizen has a "ration book location." To change this requires lengthy paperwork, and permission is given only for good cause. This network of controls makes it almost impossible to be unemployed in the city.

Not only are there restraints on rural-urban migration, but the flow of labor is sometimes in the other direction. There have been years recently in which the number of new jobs available in Canton or Shanghai was insufficient to accommodate all the school-leavers. In this event, the labor surplus is simply dispatched to the country for farm work.

The effectiveness of migration policy is suggested by the fact that the proportion of Chinese population living in rural areas has been holding steady at about 80 percent, instead of falling as one might expect in the course of economic growth.

But does the damming up of population in the countryside not mean simply that full employment in the city is achieved at the cost of growing rural underemployment? In many less developed countries, such underemployment is a chronic and growing problem. The Chinese assert that, on the contrary, their rural labor force is fully employed and that labor is scarce. If the Chinese claim is correct, the number of man-hours being worked in the rural sector today must be ***much*** larger than in 1949; and the sources of this increase need to be explored.

It appears that there has indeed been a major increase in rural employment since 1949. The main components of this increase seem to have been:

1) There has been a marked increase in the labor time devoted to infrastructure activities: roads, water control and irrigation systems, land terracing, reforestation, building of schools, hospitals, public buildings, and housing. These activities are organized mainly within a commune; but large-scale projects may be planned at higher levels and draw labor from several communes. The work is done mainly in the off-season, and helps to fill the valleys in the seasonal cycle of agricultural activity.

2) These infrastructure activities, and especially improved water control, have enabled a considerable shift of acreage from single to double cropping. They also make possible greater use of fertilizer and more sophisticated input "packages," which substantially increase crop yields. All this requires more labor.

3) Particularly in areas near city markets, there has been a diversification of production into fruits and vegetables,

poultry, eggs, milk, and meat. These activities are more labor intensive than grain growing.

4) The commune is an industrial as well as an agricultural producing unit. While the romantic vision of iron smelters in every village has understandably abated, there has been substantial development of industries which can operate efficiently on a relatively small scale. These rural industries produce partly for farm use—tractor and implement repair shops, fertilizer plants, brick kilns, cement plants, power generating units, water pumps. But they also turn out consumer goods for off-farm sale and even for export. At seasonal peaks of harvest activity, most of these industrial workers go into the fields; but their *main* activity is factory work.

5) The expansion of education, health and other public services in the rural areas absorbs substantial amounts of labor. Education is very labor-intensive, using the time of students as well as teachers. Medical and paramedical personnel in a typical commune would run into the dozens. Administrative staffs, which perform local government as well as production-management functions, are also substantial, though all except a few of the top commune officials also engage regularly in farm labor.

All in all, it appears that the claims of full employment in the rural sector are valid. Some of this employment, to be sure, has a low marginal yield per man-hour; for example, creating new land with great effort by carrying baskets of earth from some other area. The available labor time is apparently regarded as a fixed factor, and any small addition it can make to output is considered worthwhile. China is thus still a "labor surplus economy" in the sense that there are many rural workers whose marginal product is below their consumption. But until there is a demand for these workers in urban industries, their use in low-productivity rural activities is sound social policy.

VI. The Level and Distribution of Income

In considering personal income, we start from the usual distinction between its average level and its distribution among households. Following the revolution, the mass of the population experienced a once-and-for-all gain through income redistribution. Land rents, other property income, and such income sources as speculation, gambling, bribery, and extortion were abolished. Granted that the redistibution process may have affected the amount of income, it seems clear that part of the consumption of the former rich became available to lower-income groups. In the cities, a visible form of transfer was the subdivision of large private homes into multiple-family dwellings. In the countryside, income formerly paid to the landlord was available for increased consumption as well as capital formation and tax payments.

Since this initial redistribution, the average level of per capita consumption has continued to rise through the growth of national output. Perkins estimates that from 1957 to 1972, the output of manufactured consumer goods rose at about 4 percent per year. The estimate of 3 percent per year for agricultural output has already been noted. The rate of increase in educational services, health services, and other public goods has been substantial. Assuming that population has grown at no more than 2 percent per year, one can reasonably conclude that per capita consumption has been rising at 1 to 2 percent a year (probably closer to the latter figure).

Observation on a visit to China suggests that this improvement takes such concrete forms as: greater variety of diet, including a gradual increase in consumption of animal proteins; a gradual increase in the percentage of the population living in newly constructed housing; and a growing surplus of family income over basic expenditure, which can be used for unrationed clothing items, travel, and such consumer durables as furniture, bicycles, sewing machines, radios, and wrist watches.

The average level of living remains very low by Western standards; but it is not as low as suggested by *GNP* estimates converted at official exchange rates. These indicate a Chinese *GNP* per capita in the neighborhood of $150, which would imply that the Chinese have long since starved to death. The difficulty is that the official exchange rate differs widely from the purchasing power parity of the two currencies. The Yuan is grossly undervalued; and the discrepancy has been increasing as prices in the United States continue to rise while the Chinese price level remains completely stable—indeed, slightly falling.

One member of our visiting group collected a good deal of retail price information in Shanghai, Tientsin, and Peking; and because he spoke fluent Chinese, he was able also to collect some family budgets for city workers. One interesting comparison involved taking a Chinese market basket and inquiring how much a relatively well-off workers' family in Shanghai would spend on each item of consumption. This totaled 150 Yuan per month, or about $75 at official exchange rate. After returning to the United States, he estimated how much it would cost for a family in Ann Arbor, Michigan, to live *in the same way* (i.e., eating mainly cereals with very little animal products, using public transportation rather than a private car, living in a two-room apartment, etc.) The total came to about $400 per month, or $4,800 per year.

The conceptual difficulties of this kind of comparison are well known; but crude as it is, it suggests the wisdom of avoiding simply exchange rate conversions. While Chinese living standards are low, they are not abysmal.

Turning to distribution, the degree of income equalization thus far achieved in China should not be exaggerated. There are wide differences in per capita income among the rural communes, related to differences in soil fertility, water availability, climate, distance to urban markets, and other factors. Perkins reports a 1965 survey of thirteen communes which revealed that income per worker in the richest commune was 3.4 times as high as in the poorest. The average level of rural incomes is substantially below that of urban incomes. Within the urban sector, monthly incomes range from 30 to 40 Yuan a month for an unskilled factory worker to 110 Yuan for a skilled worker and as much as 400 Yuan for a top civil servant or university professor.

The Chinese have succeeded, however, in cutting off the extreme "tails" of the income distribution. There are no longer any rich people—no large houses, private automobiles, staffs of servants, expensive foreign vacations, conspicuous display of luxury. Nor are there any beggars or destitute people. No one is allowed to fall below a minimum level of living. Abolition of poverty in this sense, in a still poor and backward economy, is surely a major accomplishment.

The devices used for poverty elimination include: 1) free education and virtually free medical care; 2) a pricing system which discriminates in favor of basic food and clothing items, apartment rents, public utility services, public transportation, and other essential items, and which is reinforced by rationing of food grains, vegetable oils, cloth, and housing space; 3) an incomes policy which involves raising the lowest wage rates from time to time while leaving higher rates unchanged; 4) high demand for labor plus elimination of sex discrimination in employment, which means that city families are usually two-income families, whose combined earnings are sufficient to buy the minimum bundle of necessities; 5) special provision for the aged, including a retirement pension equal to 70 percent of previous earnings plus old people's homes for those unable to live with children. The traditional Chinese family system, under which young people live with the family and contribute to its income until marriage, while old people also remain within the family unit, is also helpful in solving the familiar American problem of the isolated, impoverished individual.

While inequalities above the minimum remain substantial, the thrust of government policy is toward whittling down these inequalities gradually over the years. The continuing increase in farm procurement prices is intended to reduce the rural urban income gap. Wage adjustments in the city typically involve raising rates for the lowest two or three labor grades without raising the top of the structure, thus compressing occupational differentials. Expansion of the supply of subsidized necessities works in the direction of equalizing *real* incomes.

VII. Commentary

A subject of perennial interest to development economists is which of the less developed countries have embarked on sustained economic growth. The usual criterion is a statistically reliable growth rate of income per capita, extending over several decades so that it cannot be dismissed as cyclical or transient. China seems clearly to meet this criterion. Income per capita has grown at a modest rate since 1949. Further, the organization of the economy and the strength of political leadership give reasonable assurance that growth will continue in the future. Greatest uncertainty attaches to the outlook for agriculture. But even here the fact that China has scarcely begun to tap the potential of modern biological-chemical innovations in agriculture provides some grounds for optimism.

There has been progress also in other dimensions of development. The crucial population problem has been faced squarely and is in course of being brought under control. Employment opportunities have been enlarged and sex discrimination in employment much reduced. Dire poverty has been eliminated, and there is a continuing reduction of income inequality above the minimum.

It would be overly facile, however, to conclude that Chinese experience provides lessons readily transferable to other *LDC*s. Economic policies cannot be wrenched out of the political and social context from which they have emerged. China did, after all, have a full-scale revolution. The willingness of the population to accept sustained hard work plus austerity in consumption, while it may in part be traditionally Chinese, depends also on a quasi-religious devotion to Maoist doctrine.

A more modest and tenable conclusion is that any *LDC* can profit from close examination of Chinese experience. Especially for the countries of South and Southeast Asia, this experience is more relevant than that of the Soviet Union or the East European countries.

The other experience which *LDC*s are usually urged to study is that of Japan. So it is worth noting that despite differences in the institutional context, there are similarities between recent Chinese development and Japanese development between, say, 1880 and 1905. In both cases one observes: 1) a marked emphasis on agricultural development, leading to output increases of about 1 percent per capita per year; 2) a marked development of rural-based industry, organized in relatively small and labor-intensive workshops, and employing mainly farm family members; 3) rapid development of transport and communications; 4) establishment of universal primary education; 5) establishment of numerous heavy industrial enterprises under government auspices, stimulated partly by military requirements.

There are also obvious differences in such matters as rate of labor transfer from agriculture, degree of involvement in foreign trade, and trends in income distribution. But China-Japan comparisons should evenutally tell us more about whether economies starting with similar factor endowments and income levels tend to follow a similar development path despite institutional differences.

A Model of Public Fiscal Behavior in Developing Countries: Aid, Investment, and Taxation

By PETER S. HELLER*

In most less developed countries (*LDCs*), the public sector's role in the planning and implementation of development projects has been considerable. The rising level of public expenditure has been fueled by capital inflows from public and private sources abroad, and by the mobilization of domestic resources through taxation and local borrowing. Recently, the effectiveness of the government's development efforts have been cast in doubt. Critics argue that foreign capital inflows have resulted in increased public or private consumption rather than increased investment, and have contributed less to growth than was anticipated.[1] Others suggest that the higher tax burden has been squandered on nonproductive forms of public consumption (see Stanley Please (1967, 1972) and L. Krishnamurty).

In this paper, I shall examine these issues by developing a cross-section time-series econometric model of the public sector of eleven African countries (Nigeria, Ghana, Zambia, Kenya, Uganda, Tanzania, Malawi, Liberia, Ethiopia, Tunisia, and Morocco). Nine of these are English-speaking or "Anglophone," and seven were former British colonies; thus one would expect strong structural similarities in their budgetary processes. With the exception of Zambia, the economies of these countries are fairly similar in their structure and level of development. Tunisia and Morocco are unusual among "Francophone" countries in the degree that their fiscal system is independent of that of France,[2] and have been included to test for behavioral differences from the other sample countries. The time period is only postindependence.[3]

The econometric model will focus on the interactions among several categories of public expenditure and of domestic and foreign revenue. The model will further distinguish between alternative *types* of aid (grants vs. loans), and alternative *sources* (bilateral vs. multilateral, private vs. public). The results suggest that aid not only increases investment, but simultaneously facilitates a reduction in the level of domestic taxes and borrowing. However, the magnitude of these effects and the precise response of public consumption to aid

Brazer, Jane Chalmers, Saul Hymans, Jan Kmenta, Richard Porter, the managing editor, and an anonymous referee. The Center for Research on Economic Development at the University of Michigan provided secretarial and financial assistance.

[1] Much of this literature has been surveyed recently, see Thomas Weisskopf (1972a,b), Gustav Papanek (1973), Keith Griffin, and John Enos and Mohammed Rahman.

[2] In other French African countries, an important share of local expenditure is financed completely out of the French government's budget.

[3] For certain countries, periods of political or military turmoil are also excluded. The time period used includes: Nigeria (1961–66), Zambia (1961–69), Uganda (1962–69), Malawi (1963–69), Liberia (1964–70), Kenya (1962–71), Ethiopia (1964–70), Tanzania (1963–71), Ghana (1964–70), Morocco (1960–70), Tunisia (1960–71). The sources of data are listed in my 1973 paper. Copies of the data series and discussion of the precise series used for each country can be obtained from the author upon request.

varies according to the type of aid. Grants have a stronger pro-consumption bias, whereas loans are more pro-investment. The model also confirms that only a small proportion of marginal tax increases is allocated to investment, with the bulk used for public consumption.

In Section I a theoretical model of public sector behavior is developed, and the data and econometric procedures used are summarized (with a fuller discussion of the econometric issues in the Appendix). In Section II the results are examined, and Section III summarizes their policy and behavioral implications.

I

One approach to an understanding of the fiscal behavior of the public sector is to assume that it reflects the actions of a set of public decision makers (i.e., a Council of Ministers, etc.).[4] We shall assume that they maximize their utility, taking into account (i) alternative uses of public resources such as expenditures for economic growth, for provision of current social and economic services, and for the maintenance of political order and stability; (ii) the distribution of total output between the private and public sector; (iii) alternative modes of domestic financing such as borrowing and taxation; and (iv) alternative types of external assistance, such as grants and loans.

In any period t, assume that the utility function of the decision makers is

$$(1)\quad U = F[I_g, (Y - T), G_c, G_s, B; A_1, A_2]$$

where I_g = public investment expenditure for development purposes

$(Y-T)$ = disposable income in the private sector (which equals gross domestic product Y less tax revenue T)

G_c = "civil" consumption in the public sector

G_s = "socioeconomic" consumption in the public sector

B = the flow of public borrowing from *domestic* sources

A_1 = total foreign grants to the public sector from all sources

A_2 = total foreign loans to the public sector from all sources

Each variable relates to time period t unless otherwise stated. All variables are in real terms.

The delineation of three expenditure categories, I_g, G_c, and G_s, reflects a functional distinction found in the budgets of many African *LDC*s. The capital budget I_g is the public sector's contribution toward the realization of economic growth targets.[5]

Socioeconomic consumption expenditures G_s include all current noncapital expenditures for socioeconomic ends, including expenditures for the staffing of schools, hospitals, and health centers, for the maintenance of roads and communication networks, for the staffing of agricultural extension or agricultural research projects, etc.[6] Theoretically, one might expect that both G_s and I_g have some impact on the rate of economic growth, but in the eyes of public decision makers, G_s is usually not regarded as investment, but as a form of consumption without developmental impact.[7]

---

[4] In this respect, the model is derivative of models used to explain the fiscal behavior of state and local governments in the United States; see Edward Gramlich and L. Krishnamurty.

[5] I_g includes gross capital formation in the public sector (i.e., buildings and construction, transport equipment, draft animals, etc.) and net loans to other sectors of the economy, with the *exception* of capital formation already included in civil consumption as defined in the text.

[6] G_s is defined to include total government consumption as defined in the United Nations' budgetary statistics, less *current* civil consumption expenditure. Thus it includes current expenditure in such public sectors as education, health, transport, and agriculture. It also includes transfers to local government units since a large proportion of such transfers is used to subsidize this type of expenditure.

Civil consumption G_c includes all other public expenditures, much of this relating to the fundamental need of the state to maintain its political existence. It includes expenditures, capital and current, for government administration, for the servicing of public debt, for diplomatic representation, and for preservation of internal and external security through the police, courts, and armed forces. A smaller fraction is for subsidies and transfers to households and other nongovernmental units.[8] In distinguishing G_c from I_g and G_s, we hypothesize that decisions on G_c are both based on a different set of decision rules and have a stronger claim on public resources.

On the revenue side, increases in the tax burden T become increasingly difficult for the public decision maker to espouse, both because of the increased administrative difficulty of collection, and because of the economic cost and political resistance engendered in countries at low income levels. Of primary importance is the assumption that the choice of tax rate is a policy instrument available to public decision makers, so that T is endogenous.[9]

Borrowing from the local capital market constitutes an alternative means of resource mobilization, although it also yields disutility to the public decision maker. The net increase in the public sector's *long-term domestic* debt B is traditionally seen as fiscally irresponsible if it occurs in more than limited amounts, and unless it is used to finance public sector investment.[10] The latter restriction will be introduced below in our constraint equations.

Finally, capital inflows to the public sector from abroad, whether public or private, bilateral or multilateral, grants or loans, are assumed to be exogenous to the public sector. Although it is possible that these governments would reject aid encumbered by onerous political or economic implications, we shall assume that this is uncommon. We shall also assume that the governments are not in a position to increase significantly the level of capital inflows beyond that actually offered. In the estimations, we shall distinguish between (i) total grants and total loans received from *all* sources (public and private); (ii) net grants and net loans received from public sources; and (iii) bilateral and multilateral aid.[11]

It will be assumed that the utility function in (1) takes the form

$$(2) \quad U = \alpha_0 + \alpha_1(I_g - I_g^*) - \frac{\alpha_2}{2}(I_g - I_g^*)^2$$

---

[7] This can be easily discerned by a perusal of the annual budget speeches of the Ministers of Finance in our sample of African countries. See the author (1973).

[8] Although expenditures for the redistribution of income admittedly arise from a different kind of political motivation, these are not yet a major expenditure in the sample of African countries under analysis. It was felt that in a budgetary decision-making framework, the criteria applied to income redistribution would be most similar to that applied to other G_c expenditure.

[9] Total tax revenue includes direct and indirect property tax revenue (income taxes, customs and excise duties, export taxes, mineral royalties, etc.), and revenue from sales of government social services, license fees, interest, dividends and profits of the government, and miscellaneous revenues.

[10] The net increase in domestic debt was used instead of the stock of outstanding public debt obligations for conceptual and practical reasons. Besides the difficulty of obtaining data on the outstanding stock of debt, the budget messages in most countries indicate a conservative fear of excessive borrowing in any period, which, perhaps irrationally, appears unrelated to the level of existing debt.

[11] The variables in (ii) above measure *official* grants and loans, respectively, received from donor nations and multilateral aid agencies, and are derived from the Organization of Economic Cooperation and Development's (*OECD*) statistics. Grants include both "grant-like" flows (net) and net official grants, reparations, and indemnification payments. Loans are net of amortization and interest. The aid measure in (iii) is a breakdown of the same aid by *source*, i.e., bilateral and multilateral. Finally, each country compiles data on total grants and loans received from all foreign sources, *public* and *private* (this includes official aid as well as supplier's credits), and this is the aid measure in (i).

$$- \alpha_3(T - T^*) - \frac{\alpha_4}{2}(T - T^*)^2$$

$$+ \alpha_5(G_c - G_c^*) - \frac{\alpha_6}{2}(G_c - G_c^*)^2$$

$$+ \alpha_7(G_s - G_s^*) - \frac{\alpha_8}{2}(G_s - G_s^*)^2$$

$$- \alpha_9(B - B^*) - \frac{\alpha_{10}}{2}(B - B^*)^2$$

where $\alpha_i \geq 0$ for all i, and where a starred variable indicates a *target* level for each variable. The functional form chosen ensures diminishing marginal utility for each of the variables I_g, G_c, G_s, B, and T as they rise above a level determined jointly by their target level and by the specific set of α parameters for each variable. It also reflects a compromise between the need for heuristic accuracy and the need for an easily estimable functional form with desirable utility function properties. The absence of any interdependence between the policy variables is its primary deficiency.

The target variables in equation (2) are assumed to be determined by the following relationships:

$$(3) \quad I_g^* = \alpha_{11} Y_{t-1} + \alpha_{12} I_p$$

$$(4) \quad T^* = \alpha_{13} Y_t + \alpha_{14} M_{t-1}$$

$$(5) \quad G_c^* = \alpha_{15} G_{c,t-1}$$

$$(6) \quad G_s^* = \alpha_{16} E + \alpha_{17} Y_t + \alpha_{18}(Y_t - Y_{t-1})$$

$$(7) \quad B^* = 0$$

where M = the value of total real imports
E = primary school enrollments (in units of 10,000 students)
I_p = real private investment expenditure

The target level of investment I_g^* is set in the context of a long-term economic development plan and is influenced by the desired rate of economic growth, the perceived role of the public sector in achieving that growth, the absorption capacity of the public sector, and the relative productivity of public sector investment. Due to the absence of comparable annual investment targets in the country development plans, I_g^* was related to instruments with which it would be highly correlated. In a Harrod-Domar framework, one can posit that for a given target growth rate, I_g^* will be positively related to the level of output in the previous period Y_{t-1}, and inversely related to total private sector investment.[12] However, there may also be positive linkages between I_p and I_g if such investments are technologically complementary.[13]

The civil consumption target G_c^* is assumed to be linearly related to its value in the previous period, reflecting the importance attached to a fundamental continuity of these activities. Several instruments were used to determine G_s^*. Since educational expenditure is a substantial fraction of G_s, primary school enrollments were used to measure the level of this activity. This expenditure is also likely to be held to a fairly constant share of total output Y_t. An accelerator mechanism may also boost this expenditure, and hence $(Y_t - Y_{t-1})$ was also tested as an instrument.[14]

The tax target T^* is determined by the anticipated level of total income and by the value of tax handles such as imports or exports. Since the government sector's expenditure program may substantially affect the level and composition of imports in a given period, imports in the previous period were used as one of the instruments for T^*. Finally, it was assumed that *ex ante*, the borrowing target is equal to zero. This would not, of course, preclude a positive level of borrowing.

---

[12] An accelerator model would suggest that the change in total output $(Y_t - Y_{t-1})$ becomes an instrument.

[13] It was also hypothesized that the level of foreign exchange reserves would determine the practicality of a given level of investment, but this variable proved statistically insignificant.

[14] Since technical assistance aid is principally used to finance the staffing of operational positions within the governments of our sample, it could be considered a substitute for the government's own financing of these positions (although it may entail financial obligations, such as counterpart expenditures). The hypothesized inverse relationship between G_s^* and technical assistance was not borne out, with a completely insignificant effect on G_s. However, this may be due to the poor quality and limited amount of data available on technical assistance.

There are both economic and institutional constraints on the set of feasible public sector decisions. The least restrictive assumption is that all revenue inflows are pooled and allocated among all expenditure categories. Specifically,

$$(8)\quad T + B + A_1 + A_2 = I + G_s + G_c$$

This is institutionally unrealistic. Most African *LDC*s not only reject borrowing for current expenditure, but are encouraged by donors to realize public sector savings through a surplus on the recurrent budget, viz., $(T - G_s - G_c) \geq 0$. This would suggest as an alternative constraint set that

$$(9)\quad I_g = B + (1 - \rho_1)T + (A_1 + A_2)$$

$$(10)\quad G_s + G_c = \rho_1 T$$

where $0 \leq \rho_1 \leq 1$. The level of $(1 - \rho_1)$ reflects the government's belief as to the maximum it can realistically "save" from the recurrent budget, and this enters as a constraint on its decisions. It is not an additional policy variable. Constraint set (9) and (10) also imply that aid cannot be used directly for public consumption. Assuming no relaxation of borrowing effort, aid flows would wholly finance investment.

In the radical literature,[15] it is contended that there is greater substitutability and that aid flows can also, *ex post*, be allocated to consumption. This may be expressed either by relating ρ_1 inversely to the level of A_1 and A_2 in a given period, or by including only $100(1 - \rho_2)$ percent of A_1 and $100(1 - \rho_3)$ percent of A_2 in (9) and the residuals in (10).[16] This suggests the following constraint set:

$$(11)\quad I_g = B + (1 - \rho_1)T + (1 - \rho_2)A_1 + (1 - \rho_3)A_2$$

$$(12)\quad G_s + G_c = \rho_1 T + \rho_2 A_1 + \rho_3 A_2$$

Maximization of U with respect to current policy variables I_g, G_s, G_c, T, and B, given levels of A_1 and A_2 and subject to constraint set (11) and (12), yields the following first-order conditions:

$$(13)\quad \frac{\delta U}{\delta I_g} = \alpha_1 - \alpha_2(I_g - I_g^*) + \lambda_1 = 0$$

$$(14)\quad \frac{\delta U}{\delta G_c} = \alpha_5 - \alpha_6(G_c - G_c^*) + \lambda_2 = 0$$

$$(15)\quad \frac{\delta U}{\delta G_s} = \alpha_7 - \alpha_8(G_s - G_s^*) + \lambda_2 = 0$$

$$(16)\quad \frac{\delta U}{\delta T} = -\alpha_3 - \alpha_4(T - T^*) - \lambda_1(1 - \rho_1) - \lambda_2\rho_1 = 0$$

$$(17)\quad \frac{\delta U}{\delta B} = -\alpha_9 - \alpha_{10}(B - B^*) - \lambda_1 = 0$$

$$(18)\quad \frac{\delta U}{\delta \lambda_1} = I_g - B - (1 - \rho_1)T - (1 - \rho_2)A_1 - (1 - \rho_3)A_2 = 0 \quad \text{and}$$

$$(19)\quad \frac{\delta U}{\delta \lambda_2} = G_s + G_c - \rho_1 T - \rho_2 A_1 - \rho_3 A_2 = 0,$$

where λ_1 and λ_2 are the Lagrangian multipliers associated with constraints (11) and (12). Equation set (13) through (19) can be solved to obtain structural equations for the estimation of the parameters of the utility function and the budgetary constraint relationships:

---

[15] See Griffin and Enos, and Weisskopf (1972a,b).

[16] The only constraint on ρ_2 and ρ_3 would be that total investment exceed the level of capital inflow and required counterpart expenditure. Obviously, an aid recipient cannot invest less than its total aid flow and counterpart commitments without facing a serious credibility problem when seeking additional aid. For our sample countries, this proves to be a nonbinding constraint.

$$(20)\quad \begin{pmatrix} G_s \\ G_c \end{pmatrix} = \begin{pmatrix} \iota \\ -\iota \end{pmatrix}\beta_0 + \begin{pmatrix} -G_c^* \\ G_c^* \end{pmatrix}(1-\beta_1) + \begin{pmatrix} G_s^* \\ -G_s^* \end{pmatrix}\beta_1 + \left\{\begin{pmatrix} T \\ 0 \end{pmatrix} + \begin{pmatrix} -T \\ T \end{pmatrix}\beta_1\right\}\rho_1 + \left\{\begin{pmatrix} A_1 \\ 0 \end{pmatrix} + \begin{pmatrix} -A_1 \\ A_1 \end{pmatrix}\beta_1\right\}\rho_2 + \left\{\begin{pmatrix} -A_2 \\ 0 \end{pmatrix} + \begin{pmatrix} -A_2 \\ A_2 \end{pmatrix}\beta_1\right\}\rho_3 + \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \end{pmatrix}$$

$$(21)\quad T = \frac{\beta_2}{\beta_3} + \frac{\rho_1\alpha_6}{\beta_3}(G_c^* - G_c) + \frac{\alpha_4}{\beta_3}T^* + \frac{\alpha_{10}}{\beta_3}\{[1-\rho_1][I_g - (1-\rho_2)A_1 - (1-\rho_3)A_2]\} + \epsilon_3$$

$$(22)\quad I_g = \frac{(\alpha_1 - \alpha_9)}{(\alpha_2 + \alpha_{10})} + \frac{\alpha_2}{(\alpha_2 + \alpha_{10})}I_g^* + \frac{\alpha_{10}}{(\alpha_2 + \alpha_{10})}\{(1-\rho_1)T + (1-\rho_2)A_1 + (1-\rho_3)A_2\} + \epsilon_4$$

where

$$\beta_1 = \alpha_8/(\alpha_8 + \alpha_6),\ \beta_0 = (\alpha_7 - \alpha_5)/(\alpha_8 + \alpha_6)$$
$$\beta_2 = \{\alpha_5 - \alpha_3 + \alpha_9(1-\rho_1)\}$$
$$\beta_3 = \{\alpha_4 + \alpha_{10}(1-\rho_1)^2\}$$

Also $[\iota]$ is a $(n \text{ x } 1)$ vector of ones and $[0]$ is a $(n \text{ x } 1)$ vector of zeros. The assumed properties of the error term ϵ_i are described in detail in the Appendix. Equations (3) to (6) indicate the instruments used to estimate I_g^*, T^*, G_c^*, and G_s^*.

Equation (20) reflects the symmetrical relationship that exists between the coefficients of the structural equations for the estimation of G_s and G_c. It was estimated first, in order to obtain estimates of the critical parameters, β_1, ρ_1, ρ_2, ρ_3, and α_{15}. Since (20) is non-linear in these parameters, and since we know that $0 \leq \beta_1 \leq 1$, equation (20) was estimated by iterating over values of β_1 between 0 and 1. The value of β_1 chosen is that yielding the *lowest* sum of squared errors in the estimations. The coefficients of the latter three terms in (20) yield estimates of ρ_1, ρ_2, ρ_3; α_{15} is obtained from the coefficient of the G_c^* term which equals $(1-\beta_1)\alpha_{15}$. On this point see equation (5). These parameters may be used to calculate the transformed independent variables in equations (21) and (22); the coefficients of these transformed variables will then yield estimates of other critical parameters of the system, viz., α_6/β_3, α_{10}/β_3, and $[\alpha_{10}/(\alpha_2+\alpha_{10})]$.

Three econometric problems arose in the estimation of this equation system. First, although we assumed that the structural coefficients are the same across countries, there may be differences in the country specific intercepts. Without careful attention to this issue, recent Monte Carlo studies by Marc Nerlove and others indicate that the uncorrected variation of the error term in a pooled cross-section time-series may cause both bias and inefficiency in an ordinary least squares (*OLS*) estimation of the structural coefficients. Using a method suggested by Nerlove and P. A. V. B. Swamy, a generalized least squares (*GLS*) estimation procedure is used to correct for this.[17] Second, if the uncorrected values of the variables are used, there appears to be heteroskedasticity with a higher variance in the estimated residuals for the larger countries in terms of population or income. By transforming the variables to a per capita basis, this problem is ameliorated. Third, since our model is a simultaneous equation system, this suggests the need for a simultaneous equation estimation procedure to obtain consistent estimators for the structural coefficients. Since our equation system is overidentified, two-stage least squares (*2SLS*) is used for each equation. These econometric issues are dealt with more fully in the Appendix.

---

[17] See Nerlove and Pietro Balestra (1966), T. D. Wallace and Ashig Hussain, and G. S. Maddala.

In the estimations, all the data have been deflated to constant 1966 prices, using each country's own *GDP* deflator.[18] To obtain readily interpretable coefficients, all variables have been converted to dollars using the current year exchange rate. Thus variables initially estimated in local currencies are sensitive to any exchange rate fluctuations. This would distort the nature of the observed statistical relationships if it caused variations in variables which were actually unaffected by a devaluation.[19] However, with the exception of Ghana, there were no significant changes in exchange rates during the period, and there were only four devaluations with respect to the dollar among all sample countries.

Finally, the distinction between the fiscal and calendar year results in varying fiscal periods across sample countries.[20] The convention used was to match all variables calculated on a calendar basis (*GDP*, imports, etc.) to the fiscal year beginning in that calendar year. This complicates the interpretation of regression coefficients since for some countries, the public expenditures are themselves calculated on a calendar basis. The justification for this procedure is pragmatic. Obtaining a moving average of calendar year data would have sacrificed at least one degree of freedom for each country, and the conceptual benefits are uncertain.

II. Econometric Results

The estimation of (20)–(22) yields the structural parameters of the utility function (2) and the constraint equations (11) and (12). Reduced form estimates of the impact of foreign capital inflow on the public sector can then be derived. The results indicate the existence of structural differences in the model parameters of the Francophone and Anglophone countries. They also reveal that inclusion of Zambia fundamentally distorts the values of the parameters. In this section, we shall examine these results more closely. The estimated equations are presented in Tables 1 and 2.

A. *Constraint Equation Parameters*

Estimation of equation (20) yields estimates of ρ_1, ρ_2, and ρ_3 for each of the alternative measures of foreign capital inflow (Table 3). Several points can be made. First, our estimate of ρ_1, the proportion of tax revenues that remain within the recurrent budget, is smaller in the Anglophone country sample than in the pooled sample, the latter including the two Francophone countries. In the pooled sample, no more than 17 percent of recurrent tax revenues flow to the investment budget, as contrasted with 22 to 34 percent for the Anglophone countries.

In both samples, there are marked differences between the share of total (public and private) grants (ρ_2) and loans (ρ_3) allocated to the recurrent budget. Whereas total grants are partially allocated to the consumption budget (with ρ_2 falling to between 0.27 and 0.38), the negative values

---

[18] An alternative deflation of the aid data by an export price deflator for the donor countries was attempted, but this led to only negligible differences in the statistical results.

[19] The appropriateness of this conversion depends on (i) the proportion of government purchases of foreign goods and services, and the source of these goods; (ii) whether aid flows are pegged to some target level of real purchasing power or to an absolute level of local or foreign currency; (iii) the frequency and severity of devaluations with respect to each country's primary trading partner; (iv) the degree of bias caused by use of a *GDP* deflator rather than an expenditure specific deflator; and (v) the degree of currency overvaluation and the policy instruments used to ration foreign currency.

[20] All *OECD* aid data are on a *calendar* year basis, whereas aid data derived from individual country statistics are for the fiscal accounting period used by the country.

[f] Samples exclude Zambia.

of ρ_3 indicate that a dollar of total loans actually pulls *nonloan* resources from the recurrent budget. Little difference emerges between the impact of official and private loans on the recurrent and capital budgets. In the Anglophone sample, *both* official and total loans draw 139 percent of their value to the investment budget ($\rho_3 = -.39$).

However, a higher fraction of official grants remain within the recurrent budget (64 vs. 27 percent). The addition of the two Francophone countries drops ρ_2 below zero (in case 2, $\rho_2 = -.15$). Finally, since bilateral and multilateral aid flows have insignificant values for ρ_2 and ρ_3, respectively, the grant and loan components within each must have offsetting influences.

When we included Zambia in the sample, the results were considerably different with more than 100 percent of total grants allocated to the consumption budget, and 172 percent of loans to the investment budget ($\rho_3 = -.72$). Since ρ_2 and ρ_3 are not significantly different from zero for official grants and loans in the samples which include Zambia, it is clear that *private* capital flows account for the strongly divergent effects of the total capital flow measures. The distorting effect of Zambia was also clear from the other equations and parameter estimates. This suggested that the structural dissimilarities in Zambia's industrial structure vis-à-vis the other sample countries has led to a marked difference in its fiscal position and in the character of its fiscal behavior.[21] Although I have not included the cum-Zambian results in the tables, I shall point out the pattern of divergence suggested by the results.

B. *Utility Function Parameters*

Estimation of (20) also yields estimates of the relative values of α_6 and α_8, the quadratic terms in the utility function associated with G_c and G_s, respectively. The lower the value of (α_8/α_6), the greater the disutility arising from sharper deviations from the expenditure target for G_c relative

---

[21] For example, with the exception of 1970, Zambia experienced a net outflow of multilateral assistance throughout the decade, yielding a strong negative multiplicative dummy in the estimation of (20).

to that for G_s. In general (α_8/α_6) is equal to 1 for the Anglophone countries and is less than 1 for the pooled sample. Hence our hypothesis that G_o expenditures have higher priority but lower variability relative to G_s is borne out *only* for the Francophone countries. In the Anglophone countries, the rate of diminishing marginal utility is the same for both expenditures. The only difference is that with $\alpha_5>\alpha_7$ (from the negative constant term of these equations), higher utility will be obtained from overachievement of G_c relative to G_s, in terms of their respective targets.[22]

The estimation of equation (21) (see Table 2) yields estimates of the relative values of α_4, α_6, and α_{10}, where α_4 and α_{10}

---

[22] This assumes that both α_5 and α_7 are also nonnegative. This condition cannot be explicitly verified from the results.

[d] $I_g=B+(1-\rho_1)T+(1-\rho_2)A_1+(1-\rho_3)A_2;\quad G_s+G_c=\rho_1T+\rho_2A_1+\rho_3A_2$

are the quadratic terms associated with tax revenues and borrowing, respectively (see Table 1).[23] For example, since α_6 and α_8 are each less than α_{10}, the results imply that additional borrowing incurs a sharper increase in disutility than the marginal gain in utility from additional units of G_c or G_s. Conversely in the Anglophone cases the additional utility from G_s or G_c falls off more sharply relative to the increase in disutility from taxation (α_6/α_4, $\alpha_8/\alpha_4 \geq 1$).

Since (α_4/α_{10}) is less than 1 in all cases, the marginal disutility of additional taxation increases at a rate less than that associated with increased borrowing. It is interesting to note the impact of including Zambia on these parameters. The ratio (α_4/α_{10}) falls substantially to under .10, indicating that copper-rich Zambia is far more averse to borrowing and amenable to increased taxation than the other African countries. Lacking the tax revenue base provided by abundant mineral resources, the cost associated with increased taxation to the latter countries is, not surprisingly, greater.

Finally, from the coefficients of equation (22) (see Table 2), one can derive an estimate of the ratio of α_2 to α_{10}. For the Francophone countries, (α_2/α_{10}) is less than 1, indicating greater disutility to increased borrowing relative to the diminished marginal utility associated with increased investment. The converse appears to hold for the Anglophone countries.

Given a consistent set of parameter estimates for the $[\rho]$ set and the quadratic terms of (1), one can also obtain the partial derivatives of taxation on borrowing and expenditure. These indicate the impact of an exogenous change in tax revenues on public sector fiscal behavior. In Table 3, it is clear that the bulk of any tax increase is allocated to consumption expenditures, with no more than 13 percent going to investment and 10 to 21 percent going to reductions in domestic borrowing. In the Anglophone sample, the two types of consumption are neutrally affected, with a stronger impact on investment and borrowing. The addition of the French countries weakens the borrowing and investment impact, with a larger share of resources going to consumption, particularly G_s.

These results also verify the fiscal interdependence between the recurrent and capital budgets. If there were complete separability of these budgets, ρ_1 would equal 1 and tax revenues would have no impact on the investment equation and vice versa; both possibilities can be clearly rejected.[24] The opposite extreme of complete fungibility between all revenue sources and expenditures appears equally invalid. Tax revenues and borrowing are not fully substitutable.

---

[23] The coefficients of equation (21) yield estimates of α_6/β_3 and α_{10}/β_3, where $\beta_3=\alpha_4+\alpha_{10}(1-\rho_1)^2$. This allows estimation of (α_6/α_{10}), (α_8/α_4), and (α_4/α_{10}).

C. *Target Parameters*

In addition to the utility and constraint equation parameters, we can obtain estimates of the target coefficients specified in (3) through (7). In the consumption equation (20), the coefficients of $G_{c,t-1}$, primary school enrollment, income, and change in income variables can be used to derive α_{15} through α_{18}, respectively.[25] The lagged $G_{c,t-1}$ term is clearly significant, and yields values of α_{15} equalling .62–.70 in the pooled sample and .83–.96 in the Anglophone sample.[26] Assuming positive values of α_5, these are reasonable values, since utility maximization would yield an optimal value of G_c above $\alpha_{15}G_{c,t-1}$. Income is equally significant with values of α_{17} between .10 and .15, which is close to the average share of G_s in total income. Primary enrollment is positively correlated with socioeconomic consumption, but is not significant at a 10 percent level. Finally, in most cases, the change in income variable is insignificant, and has little impact on any of the other coefficients in the consumption equation. Where significant, it enters with a paradoxically negative sign.[27]

In the revenue equation, income and lagged imports are used to estimate T^*. The income coefficient α_{13} is approximately .20–.30, and is clearly significant. Lagged imports have a surprisingly negative coefficient, which can perhaps be explained by the collinearity of Y_t and Y_{t-1}. Alternatively, high imports in the previous period may relax the need for import tariff revenue reliance in the present. Finally, the investment equations were estimated with and without private investment, since the shortage of data on private investment significantly reduces the sample size.[28] The private investment instrument was clearly insignificant for the Anglophone sample, but quite significant with a positive sign when Tunisia and Morocco are added (with α_{12} in the latter case equalling .24–.26). The other instrument, Y_{t-1}, was significant in all cases with α_{11} equalling 0.02–0.05.

D. *Reduced Form Estimates*

The first-order conditions (13)–(19) can be solved to obtain reduced form equations. Table 4 presents the reduced form estimates of the impact of aid on each fiscal variable. For example, grants (A_1) lead to an increase in total spending by 30 to 60 percent of the grant proceeds. The distribution of this income across fiscal variables markedly differs depending on the type of grant flow and country sample. In the Anglophone sample, *official* grants disproportionately increase consumption, with 9 percent of the grant allocated to investment relative to 40 percent for consumption. The Francophone countries differ substantially with a stronger impact on

---

[24] From the above estimates, $\partial I/\partial T$ ranges from .05−.13 for the non-Zambian samples; $\partial T/\partial I$ ranges from .2 to .5.

[25] For α_{16} through α_{18}, the estimated coefficients need to be divided by β_1; for α_{15}, they must be divided by $(1-\beta_1)$.

[26] From (20), it should be noted that a positive value of α_{15} implies a *positive* correlation with G_c and a *negative* correlation with G_s. Conversely, positive values of α_{16} through α_{18} suggest the reverse.

[27] It was argued that the $(Y_t - Y_{t-1})$ variable would positively affect socioeconomic consumption in the same way as an accelerator might positively stimulate investment. However, from our estimates on aid and investment, it may be that any such positive effect on investment is partly financed by a *reduction* in socioeconomic consumption.

[28] The following countries had data on private foreign investment: Nigeria, Zambia, Malawi, Kenya, Tanzania, Tunisia, Morocco.

[c] Excluding Zambia.

investment. Addition of private grants as reflected in the *total* grant measure had opposite effects in the two samples. In the Anglophone case, it shifts the expenditure increase toward investment; with the Francophone countries included, private grants pull expenditure toward consumption. Thus, both the source of grant and the prevailing budgetary behavior (French system vs. British system) are important determinants of how aid affects the public sector.

As would be expected, the receipt of grants leads to a reduction in taxes and domestic borrowing. The reduction in taxes appears primarily a phenomenon associated with the Anglophone countries. Inclusion of Tunisia and Morocco consistently lowers (dT/dA_1). The decrease in domestic borrowing is less than that of taxes only in the case of official grants received by the Anglophone countries. Inclusion of the two Francophone countries and of private grants strongly leads to a sharper reduction in borrowing than in taxation. Finally, when we include Zambia, the lower ratio of α_4 to α_{10} strongly reverses this pattern, with dT/dA_1 considerably larger than dB/dA_1 (dT/dA_1 equalling $-.30$ to $-.50$ relative to dB/dA_1 close to zero). In other words, when we dropped Zambia, the rise in (α_4/α_{10}) implies a greater unwillingness to either lower or raise taxes relative to the target tax burden. The greater disutility of borrowing is mirrored by the stronger negative effect associated with the receipt of external grants.

Foreign loans contribute to both an increase in total expenditure and a restructuring of the mode of domestic financing and pattern of expenditure. Considerable substitutability exists between domestic and foreign borrowing, dB/dA_2 varying between .42 and .92, with the highest value among the Anglophone countries. In both samples, the impact of loans on taxes is negative but considerably smaller than the impact on borrowing. The result is to increment total spending by less than 40 percent of the total value of the loan assistance.

The loan impact on expenditure is more striking. Loans increase investment with the strongest effect arising from the inclusion of private loans. In both samples, investment rises by 63 to 76 percent of total loans, as contrasted with 41 to 53 percent of official loans. Conversely, both types of consumption expenditure are *adversely* affected by loans. In the Anglophone sample, total consumption falls by 50 to 60 percent of the loan inflow. The Francophone countries reduce their consumption to a lesser degree (and thus reduce taxes and borrowing less as well). The inclusion of Zambia only accentuates these broad trends. The investment impact is larger, as is the corresponding consumption reduction, and there is a sharper decline in domestic tax revenues.

The differential impact of loans and grants is not surprising. Grants have a more stimulative impact on consumption, and a weaker impact on investment. Tax reductions are more likely with an inflow of grants; borrowing reductions more likely in response to a loan inflow. More surprising, *grants* have a more stimulative impact on total spending, which may reflect the unwillingness of African countries to expand public spending through a sharp increase in their debt obligations.

Finally, the reduced form estimates of bilateral and multilateral aid for the Anglophone sample reveal only negligible differences in their respective impact on the public sector. Both cause a small reduction in taxes and a larger reduction in borrowing. Both lead to increases in investment with a small negative impact on consumption.

III. Conclusions

The results obtained from the estimation of the model are instructive as to the structure of the fiscal decision-making process in the public sector of Africa, and they shed light on some recent controversies on aid, taxation, and the public sector. In this section I briefly discuss some policy and behavioral implications of the model.

1) The most reassuring aspect of the results is the confirmation of the most basic model assumptions concerning the sign and magnitude of the utility function and constraint equation parameters. They reveal the strong but not fully substitutable interdependence of the recurrent and capital budgets. Not surprisingly they confirm that public decision makers clearly differentiate in their preferences between types of expenditure and their mode of financing.

In solving for the structural coefficients, the signs are consistent with some basic behavioral assumptions. Increases in tax revenue positively influence the expenditure categories and reduce total borrowing, and vice versa. If the results had shown consistently perverse signs for these relationships, the basic model structure would have been highly suspect. This does not mean that there are no differences in fiscal preference; Zambia and the two French-speaking countries, Tunisia and Morocco, appear to react to fiscal pressures in a different way than the other Anglophone countries.

2) The partial derivatives of taxes on the other expenditure and revenue variables verify Please's contention that an increase in the tax burden is unlikely to be fully used for investment. Far more is likely to be allocated to G_s and G_c. A reversal of the Please Effect would require greater pressure on African governments to change their public sector preference map.

3) The impact of the various aid measures is fully consistent with the assumption of utility maximization, and in particular, with the assumption in (1) that I_g, $(Y-\mathrm{T})$, G_o, and G_s are superior goods, and B an inferior good. The precise effect of aid is clearly determined by the shape of the preference map, and the degree to which the recurrent and capital budgets are interdependent.

4) The attempt to focus on the public sector aspect of the "aid-savings" controversy reveals the complexity of the response mechanism to aid. Foreign loans do *not* fully increment total expenditure, but reduce both borrowing and taxation, which is consistent with the radical critique.

However, aid causes a strong shift away from public consumption and toward investment. Moreover, the reduction in public fiscal effort is primarily focused on reduced borrowing rather than reduced taxation. This is more likely to stimulate the availability of capital for private investment than would the reverse situation. Consequently, if all public domestic borrowing were matched by an equal expansion in private borrowing for investment, the effect of foreign loans on total domestic investment would be considerably higher. However, it may be equally myopic to view this negative effect on consumption as wholly beneficial. If the increase in investment comes at the expense of the maintenance and operating funds for ongoing projects, a loss in the overall marginal productivity of capital may result.

Although grant flows also positively affect investment, there is a much stronger bias toward an increase in public consumption, and indirectly, through tax reduction, of private consumption. The problem in evaluating this grant effect is that even aid proponents will agree that some proportion of aid, and particularly grants, is intended at the outset to be used for government consumption. To support the radical argument, one would have to know the size and sign of the deviation from the unknown proportion. On the other hand, the radical critique is supported by the tax reduction effect.

5) The oft-repeated assertion that a shift from bilateral to multilateral aid will induce a greater increase in investment does not appear to be borne out, at least for the Anglophone countries. Only negligible differences emerge in the pattern of expenditure and revenue changes induced by either type of aid. This does not suggest that a multilateralization of aid will not have a beneficial impact on investment and growth. Rather, it indicates that there are probably considerable differences in the type of aid given by alternative multilateral (or bilateral) agencies.

6) The study suggests that further research on the fiscal activities of the public sector in *LDC*s may be fruitful. Our utility function is relatively simple, being both additive and highly aggregative. A more detailed breakdown of the revenue sources and expenditure uses of the public sector, with a more detailed specification of the determinants of each, would be desirable. By further disaggregation, one could better comprehend the decision processes of the public sector, and the way they are influenced by foreign capital inflow.

APPENDIX

Heteroskedasticity: The structural equations in (20)–(22) were initially estimated using the original values of the variables (deflated and converted to 1966 *U.S.* dollars). In the second stage of the *2SLS* estimations, the estimated variances of the country-specific residuals appeared to be positively correlated with the size of the country in terms of output and population. The problem is corrected by reestimating the equations with the variables expressed on a per capita basis. This clearly lowers the relative dispersion in the variance of the error term for the observations of each country.

Autocorrelation: Testing for autocorrelation is not possible with the usual Durban-Watson statistic, since the data is a pooling of cross-section and time-series data. Theoretically, an estimation of the autocorrelation parameter[29] δ_i for the error term of each of the N countries ($i=1, \ldots, N$) might be appropriate, yielding N parameters to be used in a generalized least square (*GLS*) estimation of the model. For each set of observations, we estimated δ_i and the multiple correlation coefficient of the autocorrelation function for a one-period lag. The correlation coefficient is quite low for most countries ($r<.3$), implying there is probably insufficient autocorrelation to justify a further *GLS* correction of the data. Conceivably our correction for heteroskedasticity reduces the severity of the autocorrelation problem. Since the population series for any country is based on extrapolations of past trends in the birth and mortality rates, the observed growth in population embodies a constant time trend. By dividing by population, one is essentially removing part of any time trend from the data itself.

---

[29] The δ_i is normally referred to as ρ_i in the econometrics literature.

The actual equations estimated are modified in certain cases to remove variables which seemed to induce considerable multicollinearity. Although this undoubtedly introduces specification bias in the coefficients of the included variables, this was judged to be preferable to the indeterminacy which multicollinearity could introduce in the coefficients.

The Pooling of Cross-Section Time-Series Data: The pooling of a cross-section time-series data set necessitates assumptions concerning the stochastic process generating the error term for each equation and as to the similarity of fiscal behavior across countries. We assume the existence of such behavioral similarity, viz., that the structural coefficients of each equation are the same for all countries. Although this is reasonable for the Anglophone countries, the assumption is stretched with the inclusion of Morocco and Tunisia and thus we examine the validity of pooling the entire sample by also estimating separate equations for the Anglophone countries (i.e., excluding Tunisia and Morocco).

If we use an error components approach, the error term for each equation in (20) through (22) is broken down as follows:

$$\epsilon_{it} = u_i + v_{it} \quad \text{for } i = 1, \ldots, N; \quad \text{t} = 1, \ldots, \text{T}$$

where N is the number of countries and T the number of years. We shall also assume that u_i and v_{it} have means of zero, are independent for all i and t, and where

$$E(u_i u_i') = \begin{cases} \sigma_u^2 & \text{for } i = i' \\ 0 & \text{for } i \neq i' \end{cases}$$

$$E(v_{it} v_{it}') = \begin{cases} \sigma_v^2 & \text{for } i = i' \ \text{t} = \text{t}' \\ 0 & \text{otherwise,} \end{cases}$$

$$E(\epsilon\epsilon') = \sigma^2 \begin{bmatrix} A & 0, \ldots, 0 \\ 0 & A \quad\quad 0 \\ 0 & 0, \ldots, A \end{bmatrix}$$

$$A = \begin{bmatrix} 1 & \nu \ldots \nu \\ \nu & 1 \ldots \nu \\ \nu & \nu \ldots 1 \end{bmatrix}$$

where $\sigma^2 = \sigma_u^2 + \sigma_v^2$ and $\nu = \sigma_u^2/\sigma^2$.[30]

A priori one would expect this decomposition of the error ϵ_{it} to be reasonable. Specifically, despite behavioral similarity (viz., equal slopes), there may be differences in each country's intercepts u_i (reflecting different levels of development). However, the choice of estimation procedure will depend on whether u_i is assumed to be random (as above). If one expects that the country-specific intercepts are ***unchanged*** as new points are added to each country's data set, one could assume u_i to be nonrandom and estimable along with the other parameters using a dummy variable procedure. On the other hand, one might expect that u_i is random, and in this case, the Monte Carlo studies of Nerlove, Swamy, and others indicate that using dummy variables may be inefficient in terms of the relative mean square error of the estimators $\hat{\beta}$ (the remaining structural coefficients) and the degree of small-sample bias.[31]

One method suggested to determine the appropriate estimation procedure is to estimate $\hat{\nu}$, according to methods developed by Nerlove and Swamy. Swamy's method (see chapters 2 and 3) requires a specific transformation of the *error sum of squares* obtained in two regressions: (i) on the "group mean" data, and (ii) on the "deviations from the group mean" data. For a given equation ((20), (21), etc.), the corresponding error sum of squares is obtained from this pair of regressions run on the second stage of the *2SLS* estimation.

---

[30] In the econometrics literature, this is referred to as $\rho = \sigma_u^2/(\sigma_u^2 + \sigma_v^2)$, but in order to avoid confusion with our model parameter ρ, we shall use ν.

[31] It should be noted that these Monte Carlo studies focused on this problem in a single equation context. It is not clear whether application to a simultaneous equation problem will change the conclusions significantly. See Maddala.

The Nerlove procedure obtains $\hat{\rho}$ by estimating the variance σ_u^2 of the dummy term coefficients as a proportion of σ^2. The latter equals σ_{ui}^2 *plus* the remaining variance σ_{vi}^2 in the dummy variable equation. Since the Swamy and Nerlove estimates of $\hat{\rho}$ prove considerably different in several cases, $\hat{\rho}$ was calculated as the average of the alternative estimates. Given alternative values for $\hat{\rho}$, the number of time periods, and the number of countries, the Monte Carlo studies of Nerlove and Swamy provide small-sample measures of the relative efficiency of *OLS*, *OLS* with dummy variables, and the *GLS* procedure using $\hat{\rho}$.

In general, if $\hat{\rho}$ is close to 1, the use of *OLS* with dummy variables is the best estimation procedure; if $\hat{\rho}$ is close to zero, *OLS* without dummies dominates. I calculated $\hat{\rho}$ values for each equation in (20) through (22), and transformed the variables in the second stage of the *2SLS* estimation procedure according to the procedure indicated as most efficient in the Swamy-Nerlove studies.[32] These transformed variables were then used as inputs to the estimations of equation system (20)–(22). In other words, the variables in each half of the vector in (20) and the whole vector in (21) and (22) were initially transformed according to the Nerlove-Swamy procedure.

---

[32] The values of ρ for each estimation are specified in Tables 1 and 2. If ρ was close to 1, dummy variables were used for that component of the variable.

Demand for International Reserves and the Optimum Mix and Speed of Adjustment Policies

By EMIL-MARIA CLAASSEN*

Do central banks behave rationally with respect to their holdings of international reserves? Casual observation would indicate that countries do not take steps to compensate losses in international reserves until their reserves go down below some critical lower level. On the other hand, the behavior of some notorious surplus countries would indicate a nearly insatiable appetite for foreign reserves, somewhat reminiscent of "Mrs. Machlup's Wardrobe Theory of Monetary Reserves" as Robert Clower and Richard Lipsey, p. 587n, termed it. However, there is no need to resort to dilettantish psychiatry if positive economic analysis can explain this asymmetrical behavior. There is some upper level, below infinity, where central bankers do take action to reduce reserves to a target level even though this upper level may be a greater absolute distance away from the desired amount than is the critical lower level. The purpose of this paper is to show one possible optimization procedure of reserve management that would explain less frequent balance-of-payments adjustment policies above the target level of reserves than below it. Furthermore, this optimizing procedure would also explain abrupt, highly discontinuous, as opposed to smooth, balance-of-payments policy changes.

I. The Optimum Combination of Balance-of-Payments Adjustment Policies

The basic context is that of a country which possibly experiences considerable deficits and surpluses due to random disturbances, but is in "fundamental balance-of-payments equilibrium." The actual balance-of-payments surplus or deficit B is composed of a random component ϵ and a desired component B^*, induced by policy actions:

$$B = \epsilon + B^* \tag{1}$$

where B is the actual change in the level of reserves R; that is, $B = \Delta R$. *Starting from an initial position of equilibrium*, $R = R^*$, any deviation ϵ of actual reserves R from desired reserves R^* may be counteracted, partially or totally, by policy actions:

$$B^* = -\gamma\epsilon \qquad 0 \leq \gamma \leq 1 \tag{2}$$

where γ stands for the policy response coefficient equal to $dB^*/d\epsilon$. If we let X stand for a balance-of-payments policy-induced variable, we then can say

$$\gamma = \frac{dB^*}{dX}\,\frac{dX}{d\epsilon} \tag{3}$$

Thereby we discriminate between the impact of the random disturbance on the policy variable, $dX/d\epsilon = \beta$, and the impact of the policy variable on B^*, $dB^*/dX = \alpha$:

$$\gamma = \alpha\beta \tag{3a}$$

We also abstract from the lagged influence of the random disturbance on policy β as well as the lagged influence of policy on reserves α.

All use of a policy variable X in order to influence the balance of payments will be only temporary because of our assumption of a fundamental balance-of-payments equilibrium. The mean value of

$$dX = \beta\epsilon = \gamma\frac{\epsilon}{\alpha} \tag{4}$$

will be zero. The variance of X

$$V(X) = E(dX^2) = \gamma^2\frac{V(\epsilon)}{\alpha^2} \tag{5}$$

expresses the variability of the policy variable, or in terms of the standard deviation:

---

* Professor of economics, universities of Paris-Dauphine (France) and Giessen (Germany). The paper was written in 1973 during a stay as visiting professor at the University of Pittsburgh.

$$S(X) = \gamma \frac{S(\epsilon)}{\alpha} \tag{6}$$

$S(X)$ represents the return of holding reserves since higher reserves decrease the necessity of adopting internal adjustment policies (lower β, and hence, for a given value of α, lower γ), thus decreasing the variability of X.

Whatever tradeoff central bankers may choose between financing a deficit or disposing of a surplus via reserves, on the one hand, and making the adjustments necessary to avoid a change in reserves, on the other hand, one element in their decision is the choice of the adjustment policy(ies) among the menu of available policy actions. The recent models of the demand for reserves developed by Peter Clark and Michael Kelly are only concerned with expenditure-changing policies. Based on these models, the internal adjustment cost consists exclusively of the variability in the level of income. Hence, in terms of equation (6), the policy-induced variable X is nominal income and the coefficient α stands for the marginal propensity to import; accordingly, the internal adjustment cost varies negatively with the openness of the economy. However, a policy of altering income may be extremely costly—particularly for those economies that are not very open—in comparison, for instance, to an interest rate policy. Thus, a more appropriate response to a temporary deficit may be a temporary rise in the interest rate leading to net capital inflows and to a higher transfer of interest payments to foreigners reducing disposable income. The relevance of the openness of the economy would then depend on the capital account, i.e., on the sensitivity of capital flows to changes in the interest rate. While income changes caused by the expenditure-changing policies are some multiple of the desired change in the balance of payments, changes in disposable income may be only a fraction of the desired change in the balance of payments.

The problem of the choice of adjustment policies among the various types of expenditure-changing and expenditure-switching policies in the government's arsenal of possible measures must be solved on the grounds of cost-benefit analysis. The optimal choice could conceivably be different in a deficit than in a surplus situation. Thus, because of reluctance to create any unemployment, an expenditure-increasing policy could be chosen during surpluses and a tight interest rate policy during deficits. On the other hand, several instruments may be used simultaneously in either situation because of diminishing returns to any policy instrument on the basis of absolutely and relatively increasing internal adjustment cost. Such diminishing returns would induce a combination of policy actions. Even without such diminishing returns, each instrument may damage a different group of individuals within the community so that the government may be keen to employ several instruments in order to disperse the "burden of adjustment" equitably in the community.

An alternative and even stronger argument for the optimum combination of adjustment policies can be made outside of the assumed world of certainty of response of the balance of payments to any adjustment policy. William Brainard has shown that under uncertainty if two (n) instruments are available to hit one target it will generally be optimal to use a combination of both (n) instruments. Under uncertainty, the attainment of B^* is then an expected value. Admittedly, the utilization of one policy instrument could attain the target B^* but only with the risk of undershooting or overshooting. In the presence of two policy instruments, the risk will be reduced. Even if the second policy instrument has the same degree of risk as the first, the principle of economies of diversification applies if we assume imperfect correlation between the impacts of the two instruments. Thus the optimum "portfolio" of balance-of-payments adjustment policies will generally include the utilization of all n available instruments.

II. Discontinuous and Asymmetrical Balance-of-Payments Adjustments

In reality, we observe that governments

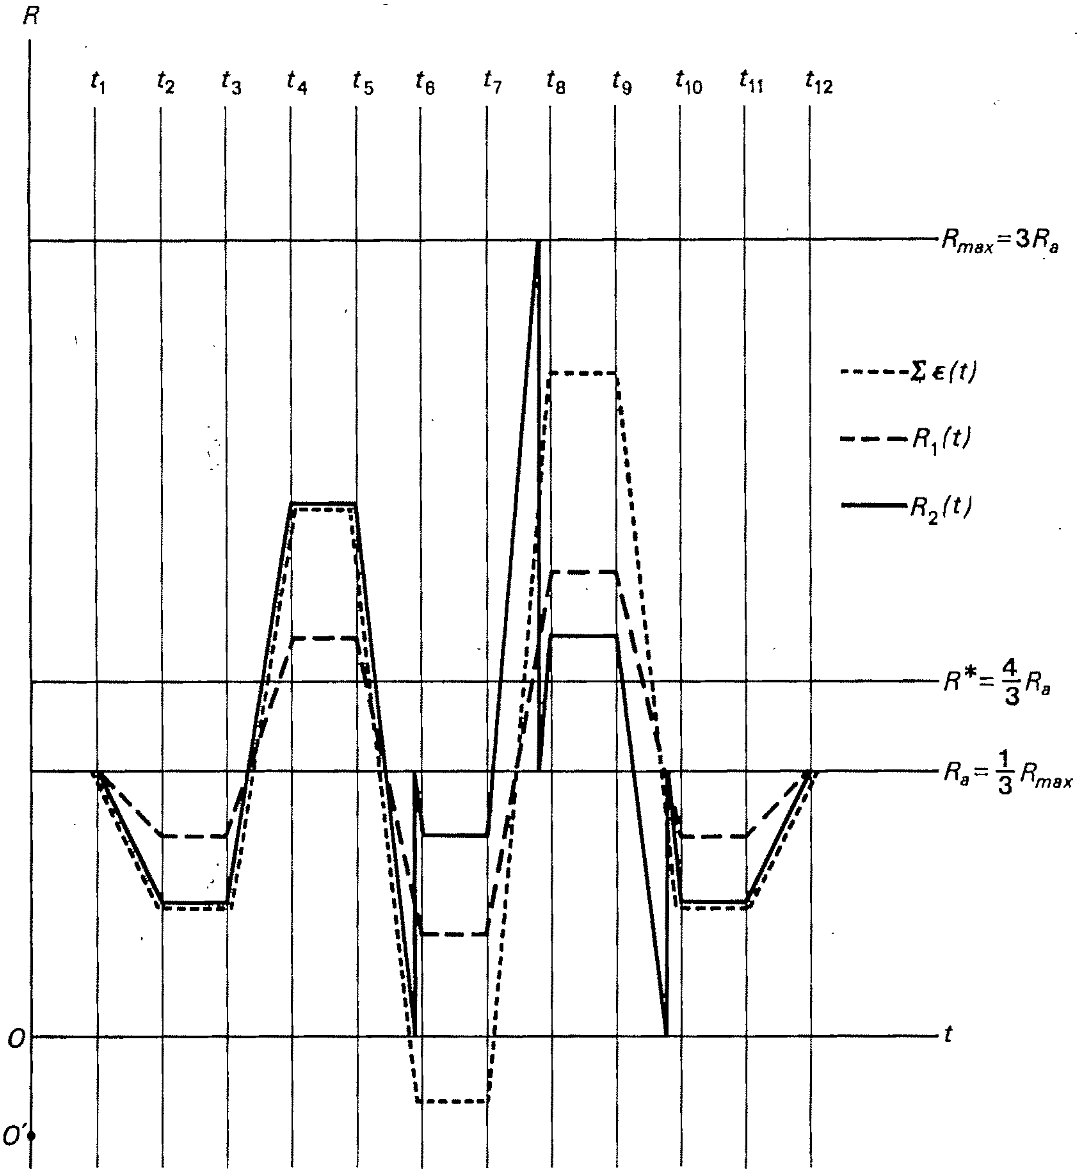

FIGURE 1

not only pursue a combination of balance-of-payments adjustment policies, but that they react discontinuously, and asymmetrically in the cases of surpluses and deficits. Only when reserves go outside certain limits do governments use their policy instruments of adjustment, and they respond faster to a deficit than a surplus.

Figure 1 illustrates one possible speed of adjustment policy in the alternative cases of continuous and discontinuous adjustment. The dotted line indicates one possible time-series of the cumulative random disturbance in the balance of payments, $\sum\epsilon(t)$. Thus, in period t_1t_2 there is a continuous deficit (the exchange rate is at the floor) and the monetary authorities intervene by selling foreign exchange. In period t_2t_3, there is neither a deficit nor a surplus and from t_3 until t_4, the exchange rate is at the ceiling causing renewed intervention by the central bank in the foreign exchange market, this time in order to buy foreign exchange, and so on. If there is a continuous adjustment as the Clark-Kelly model suggests "for analytical sake of simplicity," and this adjustment is a simple linear one (implying that only a fixed proportion of reserves outflows and inflows are neutralized), then the line $R_1(t)$ reflects the behavior of the level of reserves. The vertical difference between $R_1(t)$ and $\sum \epsilon(t)$ measures the continuous correction of deficit or surplus by internal policy actions ($\gamma = 0.5$) on the assumption of the instantaneous influence of these actions on the balance of payments. Line $R_2(t)$ illustrates discontinuous adjustment where the government takes supposedly once-and-for-all internal adjustment measures to bring back the level of reserves to some desired level, say R_a, whenever the reserve level reaches certain lower and upper limits, shown as 0 and R_{max}, respectively, in Figure 1. The assumption that the adjustment policies have an immediate impact on the balance of payments justifies setting the lower signal-point for policy action at zero. A more realistic analysis would set this lower limit at some positive level (say at 0 by shifting the origin of the coordinates to 0′) in the light of problems of uncertainty and possible overshooting and undershooting.

A "discrete-time" adjustment in the sense of less frequent adjustments, but at larger lots, could be justified by pointing out that the random disturbances in one definite direction may soon be reversed so that any "continuous-time" adjustment of the type $R_1(t)$ would be in many cases redundant (and more costly in terms of a higher variability of some internal variables). Only if the disturbance has, for a certain time interval, a definite one-way tendency, will it be necessary to adopt internal policy measures. The main point is that the choice of the "reserves-management rule" (0, R_a, R_{max}) described in Figure 1 can explain the asymmetry in adjustment behavior with respect to surplus and deficit cases, since this rule implies that $R_{max} = 3R_a$.

The above rule can be derived from the analysis of Merton Miller and Daniel Orr of the demand for precautionary cash balances by firms whose payments *and* receipts are timed irregularly (as is the case for central banks). The analysis also involves the assumption that the firms manage their cash balances under some "policy of simple form" (as has been suggested that central banks ought to do). Miller and Orr assume that the probability distribution of the net cash flows has a zero mean, which is in line with our assumption of fundamental balance-of-payments equilibrium. For the hypothesis of a discontinuous cash-management policy (with discontinuous portfolio transfers from bonds to cash or from cash to bonds), they derive two important formulas from probability theory. The first one concerns the probability of a portfolio transfer, $P(A)$—or in our context the probability of a balance-of-payments policy adjustment—and the related question of the probable number of times that reserves (cash) will hit either the upper limit R_{max} or the zero lower limit. The formula for $P(A)$ is:

$$P(A) = \frac{V(\epsilon)}{R_a(R_{max} - R_a)} \tag{7}$$

The second formula concerns the average level of reserves (cash):[1]

$$R = \frac{R_a + R_{max}}{3} \tag{8}$$

There are now two problems to be solved. The first is that of the *relative* level of R_a and R_{max}, or the optimal ratio R_{max}/R_a. The second concerns the *absolute* level of R_a and R_{max}, or the optimum amount of average reserves holdings, R^*. The solution of the first problem is rather easy because it is independent of any return-cost comparison. By definition, R_{max} must exceed R_a; the question is by how much. Suppose that we know the average desired level, R^* (the solution of which will be analyzed later on). According to (8), many possible combinations of R_a, R_{max} will satisfy the equilibrium R^*, and in this respect the ratio R_{max}/R_a is independent on any return-cost comparison given the amount of R^*. Based on (7), the particular combination chosen will set the expression $R_a(R_{max}-R_a)$ at its maximum value, and hence $P(A)$ at its lowest level, subject to the constraint $R^*=(R_a+R_{max})/3$. Condition (8) implies that $R_a(R_{max}-R_a)$ is equal to $3R^*R_a-2R_a^2$; thus we have to maximize this expression with respect to R_a, yielding:

---

[1] The derivation of the above formulas (and possible extensions of them) necessitates a rather lengthy and cumbersome analysis in terms of probability theory. The reader interested in the step-by-step derivation should consult Miller and Orr, pp. 420–23, and Orr, pp. 58–60.

$$R^* = \frac{4}{3} R_a \tag{9}$$

Then setting the value of R^* given by (8) into (9), we obtain:

$$R_{max} = 3R_a \tag{10}$$

The asymmetrical properties of optimal central banks' reserves-management policy then follow. Downward adjustments in reserve holdings, while larger than upward adjustments, are also, of course, less frequent, which is why R^* is not affected by the asymmetrical nature of the solution for R_{max}, given $R_{min}=0$.

We turn to the determination of the average volume of desired reserves R^*, and hence, of the absolute levels of R_a and R_{max}. It can only be solved on the basis of a return-cost comparison. But the return and cost components of reserve holdings have different dimensions. The costs are measured in terms of traditional pecuniary opportunity costs, while the return is expressed by the variability of some internal variables. Therefore one cannot continue the analogy between the optimum amount of reserves and the optimum amount of precautionary cash balances. In contrast to the inventory approach to the demand for money which derives the optimum volume of cash balances by a simple cost-minimization procedure, the demand for reserves is essentially the outcome of the utility-maximization principle.

Let us first look at the "technical" tradeoff between average reserves holdings R and the probable optimal number of adjustments in the reserves $P(A)$. Formula (7) can be rearranged as follows by taking into account our expressions (9) and (10) regarding the relations between R^*, R_a, and R_{max}:

$$P(A) = \frac{V(\epsilon)}{R_a(R_{max}-R_a)} = \frac{V(\epsilon)}{2R_a^2} = \frac{16}{9}\,\frac{V(\epsilon)}{2R^2} \tag{7a}$$

or

$$R = \frac{4}{3}\,\frac{S(\epsilon)}{[2P(A)]^{1/2}} \tag{11}$$

This relationship traces the asymptotic tradeoff curve in the southwest panel of Figure 2. As R increases, the probability of internal adjustment policies to restore reserves to the level R_a becomes smaller.

The optimal point on the tradeoff curve depends on the returns relative to the costs of reserves holdings. The *return* consists of the foregone costs of adjustment, as represented by the variability of some variable X:

$$S(X) = P(A)\frac{S(\epsilon)}{\alpha} \tag{6a}$$

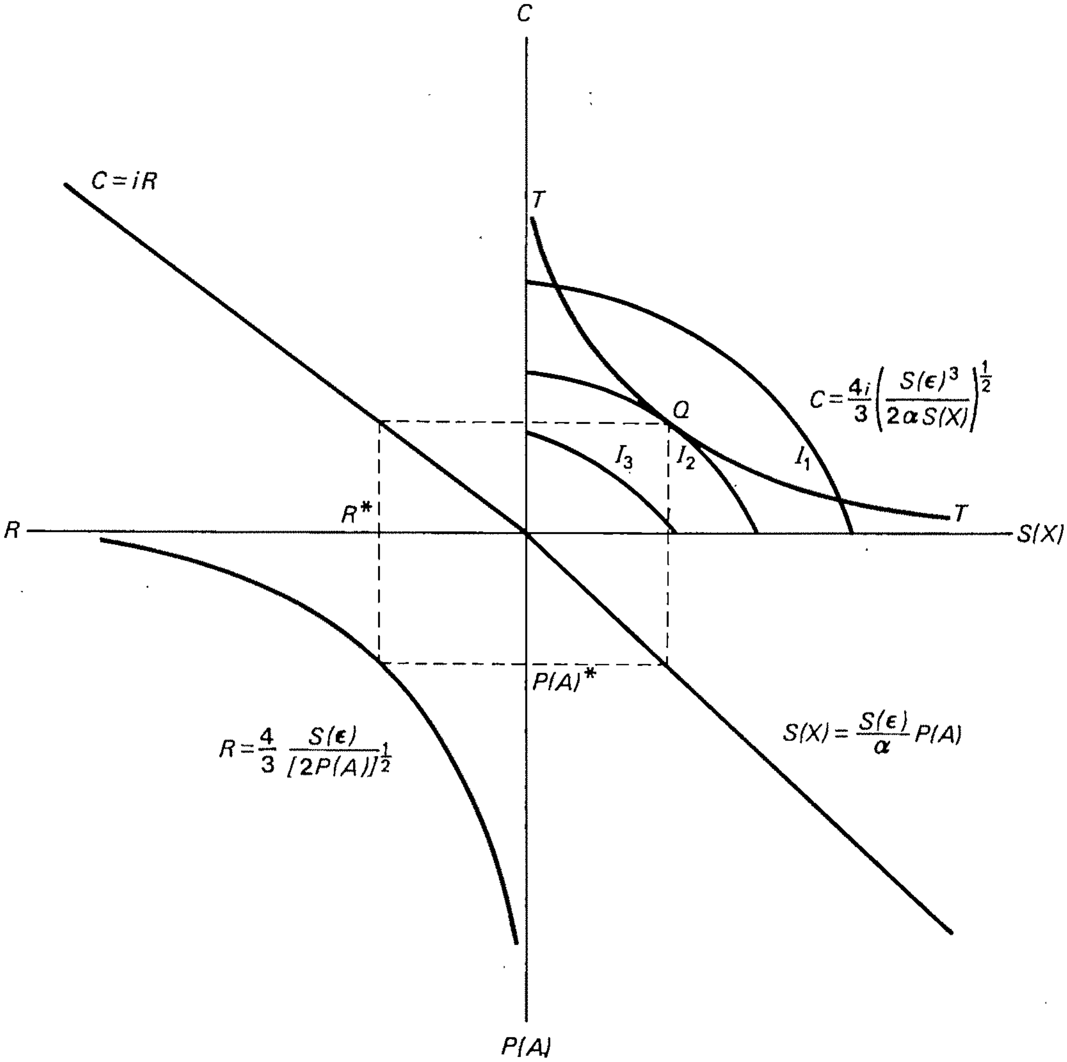
Expression (6a) corresponds to (6) provided that γ is replaced by $P(A)$. However, $P(A)$ continues to be equal to $\alpha\beta$ by analogy with formula (3a). Relation (6a) is represented as a straight line in the southeast panel of Figure 2. Higher reserves lead to less frequent adjustments, thus to the benefit of a lower variability of some internal variables.

The *cost* element of reserves C is equal to the difference between the return the reserves could earn on alternative, domestic or foreign, investments and the positive yield paid on reserves. Denote the net opportunity cost per unit of reserves i; then total cost of reserves will be

$$C = iR \tag{12}$$

The cost function is plotted in the northwest panel of Figure 2.

Now, the technical tradeoff between R and $P(A)$ can be translated into a tradeoff between C and $S(X)$ by setting the value of R given by (11) into (12) and replacing $P(A)$



C
C=iR

by its value indicated in (6a):

$$C=\frac{4i}{3}\frac{S(\epsilon)}{[2P(A)]^{1/2}}=\frac{4i}{3}\left(\frac{S(\epsilon)^3}{2\alpha S(X)}\right)^{1/2} \tag{13}$$

Relation (13) is traced in the northeast panel of Figure 2 as the transformation curve TT. Which cost-return combination the central banker will choose depends on the country's preference function:

$$U=U[C, S(X)] \qquad \frac{\partial U}{\partial C}<0, \frac{\partial U}{\partial S(X)}<0 \tag{14}$$

traced as a set of concave indifference curves in the northeast panel of Figure 2. The shape of the curves assures the attainability of a unique equilibrium at the tangency point Q generating the equilibrium value for the average reserves holdings R^*, and for the rate of balance-of-payments adjustment policies $P(A)^*$.[2]

---

[2] By differentiating (14) and setting $dU=0$ we obtain the slope of an indifference curve I:

$$\frac{dC}{dS(X)}=\frac{\partial U/\partial S(X)}{\partial U/\partial C}$$

This derivation of the "optimum speed" of adjustment policies gives rise to a target level of reserves (R_a), which will be restored discontinuously depending upon when actual reserve movements hit some maximum level (R_{max}) or fall to some minimum level (zero). The maximum level, as shown, is always three times higher than the target level. The *absolute* amount of the target level (R_a), and therefore the absolute amount of the maximum level of reserves and of the average level of reserves (R^*); depends directly on the variability of international payments $S(\epsilon)$ and the internal adjustment cost $S(X)$ and inversely on the interest rate i. The solution also depends on a certain degree of openness of the economy α and a certain "taste" of the "collectivity" regarding the two "bads": domestic income loss due to higher reserves, and internal adjustment cost due to lower reserves.

III. Summary and Conclusion

The suggested model of the demand for reserves is based on government welfare maximizing behavior under uncertainty. Random disturbances in the balance of payments can either be financed with reserves or eliminated by changes of internal variables provoked by so-called balance-of-payments adjustment policies. Thus, there is an "objective" tradeoff between reserves and adjustment policies on the one hand and a "subjective" tradeoff between the opportunity cost of reserves holdings and the variability of internal variables induced by adjustment policies on the other hand. This basic idea can be found in the fundamental contributions of Clark and Kelly. Their basic assumptions, however, are a caricature of actual central bankers' behavior. On the one hand, the monetary authorities are not restricted to expenditure-changing policies as a means of altering reserve holdings. In addition, diminishing returns or increasing disutilities from larger doses of any adjustment policy call for a mixture of available adjustment policies. Uncertainty is another factor breaking down the simple pairing of n instruments with n targets and argues for the efficiency of assigning several adjustment policies to the balance-of-payments target on the basis of the ordinary diversification principle. Another set of issues arises concerning the speed of implementation of this "optimum mix" of adjustment policies, which is neither continuous nor symmetrical above and below the desired level of reserves. It is not irrational for central banks to give high priority to the internal stability target in case of temporarily persistent balance-of-payments surpluses and to give equal priority to internal and external stability targets in case of persistent deficits. Central banks also may be right not only to adjust discontinuously (since adjustment should take place only if actual reserve movements

---

This is the rate at which the country would be willing to accept higher opportunity cost for lower internal adjustment cost. By differentiating (13) with respect to $S(X)$, we obtain the slope of the transformation curve TT:

$$\frac{dC}{dS(X)} = \frac{2i}{3}\left(\frac{S(\epsilon)^3}{2\alpha S(X)^3}\right)^{1/2}$$

which translates the "technical" ratio of the tradeoff between higher opportunity cost and lower adjustment cost. At point Q, the point of the constraint utility maximization, the ratio of the marginal disutilities is equal to the technical ratio of the marginal tradeoff:

$$\frac{\partial U/\partial S(X)}{\partial U/\partial C} = \frac{2i}{3}\left(\frac{S(\epsilon)^3}{2\alpha S(X)^3}\right)^{1/2}$$

A very special case of the country's utility function would be where the marginal rate of substitution of C for $S(X)$ is equal to -1 on each point of the indifference curve. Hence, the indifference curves would be straight lines with a slope of -1. In this special case the equilibrium point would be where:

$$\frac{2i}{3}\left(\frac{S(\epsilon)^3}{2\alpha S(X)^3}\right)^{1/2} = 1$$

This overly restrictive hypothesis would result in a "cube-root law," familiar in the demand for precautionary cash balances and now (partly) applicable to the demand for reserves. In substituting the value of $S(X)$, given by relation (6a) in the above formula, and after having substituted the value of $P(A)$ indicated by equation (7a) in (6a), we obtain the demand-for-reserves function

$$R = S(\epsilon)\left(\frac{16}{9\alpha i}\right)^{1/3}$$

Alternatively, we could have derived the same formula by forming the *total* cost function $K = S(X) + C =$ (6a) $+$ (12) where C is considered as equivalent to the cost dimension $S(X)$. If we differentiate K with respect to R and set $\partial K/\partial R = 0$, we obtain the same cube root formula for the demand for reserves.

hit some ceilings or fall down to some critical minimum), but to respond less frequently, and in larger doses in surplus situations than in deficit situations.

This paper has made extensive application of monetary theory to international monetary phenomena. There is nothing new about such an endeavor even though some authors are not quite conscious about the possible analogies between these two fields of research. There are many similarities between the demand function for precautionary balances by individuals and the demand function for international reserves by central banks. The main difference between the two functions that is recognized in this paper is the use of a notion of internal adjustment cost in the demand for reserves as opposed to the idea of cost of portfolio shifts in the precautionary demand for money. Note, however, that even in modern monetary economics, payments patterns are not always treated as imposed upon the individual. Quite the contrary, in the case of inflation or of interest payments on money, these patterns are considered as highly flexible. The only difficulty in applying the same idea of flexible payment patterns to the central bank demand for reserves is the need to conduct the analysis in terms of social preferences as opposed to simple cost minimization because of the lack of a proper pecuniary dimension for costs.

The Hereditary and Relativistic Formulation of the Demand for Money: Circular Reasoning or a Real Structural Relation?

By M. ALLAIS*

The March 1972 issue of this *Review* carries a note by J. L. Scadding on various aspects of the reformulation of the Quantity Theory of Money which I have put forward.[1] Although his comments seem to me to rest on factual errors and paralogisms, they are well worth discussing, for Scadding's view of the basic significance of the new hereditary and relativistic theory seems to be shared by some economists.

It is no easy task to determine the main lines of Scadding's analysis. I think I do him no injustice in singling out the following points. He claims that: a) the weighting system used in the new theory is tantamount to carrying out a lagged regression of the velocity of circulation against itself, which would explain the good results obtained as being a necessary consequence of the formulation, and so destroy any value they might have for analysis of the demand for money. b) It therefore matters little whether one chooses to consider the rate of increase of global expenditure rather than that of prices, since the effect of either tends to "wash out" in the fitting process. c) There is some circularity in the computations, and this would explain the good results obtained. In dealing with Scadding's criticisms, I shall start by recalling the essential features of the new theory (Section I), and go on to review the factual errors in (Section II), and paralogisms (Section III) in his presentation.

I. The Essence of the Hereditary and Relativistic Theory of the Demand for Money

To clarify the critique which follows and avoid possible confusion, a few lines must first be devoted to setting forth the essential contents of the theory I have presented.

1) *The Basic Formulation of the Hereditary Relativistic Theory.* The coefficient of psychological expansion Z is defined as

$$(1)\quad Z(t)=\int_{-\infty}^{t} x(\tau)\exp\left[-\int_{\tau}^{t}\chi(u)du\right]d\tau$$

where $x(t)$ and $\chi(t)$ denote the rate of increase of global expenditure and the rate of forgetfulness at time t, respectively.

The rate of forgetfulness is derived by applying a number of simple and economically appealing economic postulates as

$$(2)\qquad \chi/\chi_0 = 1/\psi(Z) = (1+e^{Z})/2$$

in which χ_0 is the value of χ for $Z=0$. The estimate of M^* (the estimated value of the money supply) is taken as $M^*=\phi_0 D\psi(Z)$ where ϕ_0 is a constant, D is total expenditures.

It should be stressed that the economically significant parameter in this formulation, contrary to Scadding's assumption, is the psychological rate of expansion Z, and not the rate $z=\chi_0 Z$ (Scadding's relation (3), p. 152). Z is an estimate of the cumulative memorized effect of past changes in total expenditure. In no event is it proper to interpret z as "the expected rate of change of . . . nominal output" as Scadding does (p. 151). The only valid interpretation is that it is the rate of change of global expenditure which one is accustomed to. This is a psychological parameter of a hereditary nature, and it has nothing to do with any prediction of the future. More generally, most of the quantities carrying the adjective "expected" in the current literature do not represent in any sense what this label purports to indicate they should.[3] The hereditary and relativistic theory cannot usefully be approached taking currently accepted theories as the frame, for it differs *completely* from them in a number of fundamental respects.

2) *Fitting Method.* Admittedly, a superficial reading of expression (1) for Z *at first sight* can give the impression of circularity. From (1), Z depends on past values of χ, and from (2), χ is a function of Z. Nevertheless, it is easy to verify that there is no circularity in the fitting process. In fitting, *only* the differential equation

$$(3) \qquad (dZ/dt) + \chi Z = x$$

is used. This is equivalent to relation (1), and the procedure used is to carry out the approximate integration of this relation taking a given value Z_1 as starting point. Thus *for given values of ϕ_0 and Z_1, the computation of M^* depends only on the successive values of global expenditure, and is therefore completely independent of the values of M. The very good fits obtained indicate that there is a complex interdependence between the two series M_n and D_n and that its structure corresponds to that corresponding to the new theory.*

The foregoing shows that appraisal of the scope of the circularity argument derived from considering relation (1) must in fact focus on the differential equation in relation (3), which is the only relation entering the computational process. Furthermore, given the *essential* role played by the values of x in the approximate integration of this equation, it is far from a matter of indifference whether the rate of increase used is that of global expenditure x or prices p.

3) *The Velocity of Circulation.* My own view is that in discussing the hereditary and relativistic theory, it is better to consider the quantities M and M^*, the observed and estimated values of the money supply, rather than V and V^*, the observed and estimated values of the velocity of circulation. Consideration of the series D and V rather than D and M complicates the discussion needlessly, since with $V=D/M$, velocity V depends simultaneously on both D and M. However, as Scadding has brought the discussion onto the latter ground, it is appropriate to consider the implications of the hereditary relativistic theory if the focus of the discussion is V, the velocity of circulation, and not M, the money supply.

To the estimate of M given by $M^*=M_D$, there corresponds the estimate V^* of the velocity of circulation V. We have

$$(4) \qquad V^*/V_0^* = 1/\psi(Z) = (1+e^Z)/2 = \chi/\chi_0$$

where V_0^* represents the value of V for $Z=0$. Equations (3) and (4) show clearly that the calculation of V^* is based not on past values of V but on past values of x. To provide an illustration, Charts I and II present the two fittings for the velocity of money derived using the new theory, for the United States 1918–41 and for Germany from December 1919 to October 1923. Both fittings use exactly the same law, and call on only two arbitrary constants, ϕ_0 and Z_1. The agreement between the calculated and observed values is all the more remarkable for this reason. This agreement should be enough on its own to eliminate any suggestion of spurious correlation.

Putting $v=(V-V_0^*)/V_0^*$ and

$$(5) \qquad v^* = (V^* - V_0^*)/V_0^* = (e^Z - 1)/2$$

we derive from (3) and (4)

$$(6) \qquad [2/(1+2v^*)]dv^*/dt + \chi_0(1+v^*) \log(1+2v^*) = x$$

This equation expresses the complex interdependence linking the values of v^* and those of x. If instead of Z, we consider v^*, the integral equation (1) can be written

$$(7) \qquad \log(1+2v^*) = \int_{-\infty}^{t} x(\tau) \cdot \exp\left[-\int_{\tau}^{t} \chi_0[1+v^*(u)]du\right] d\tau$$

This equation is an integral equation which provides an implicit definition of x as a function of v^*, and vice versa. In terms of the present discussion, (6) is to be preferred to the equivalent relation (7), since it gives the

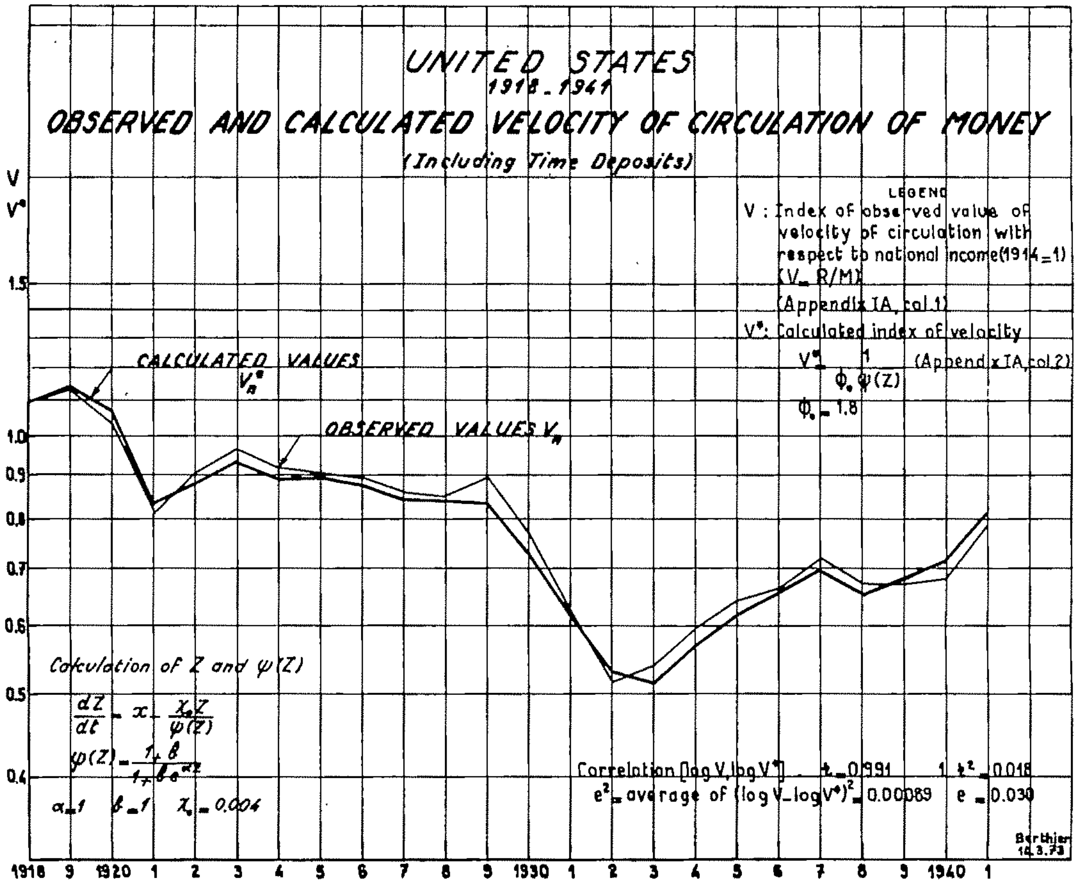

Figure 1

expression of x as an explicit function of v^*, and avoids any appearance of circularity.[3]

II. Estimated and Observed Data—Factual Errors in Scadding's Analysis

The points made by Scadding are based on factual errors which vitiate his reasoning.

1) *Confusion Between the Observed and Estimated Values V and V* of the Velocity of Circulation.* In the first instance, Scadding unfortunately fails to make the distinction between the observed and estimated values V and V^*. In fact, his mathematical reasonings are valid *only if V and v are replaced therein by V* and v**. In using V and v instead of V^* and v^*, he implicitly assumes that the relative deviation of V from V^* remains small[4] which is equivalent to assuming that the hereditary and relativistic theory gives good results. In addition, he makes the further implicit assumption that the same is true for the various higher order derivatives of V and V^*, whereas in point of fact, *the relative deviations are the greater the higher the order of the derivatives considered.*[5] For both of these reasons, Scadding's mathematical

---

[3] At first sight, relation (7) may seem to smack of circularity even more than relation (1). But it must be repeated here, as was noted in Section I.2) above, that the fitting method used demonstrates clearly that there is no circularity (see also Sections III.2) and III.3)).

[4] The implications of this *absolutely essential* assumption are examined in detail in Section III.2).

[5] Since the number N considered by Scadding is very large, there is actually *no justification at all* for treating $D^n v$ and $D^n v^*$ as though they were the same.

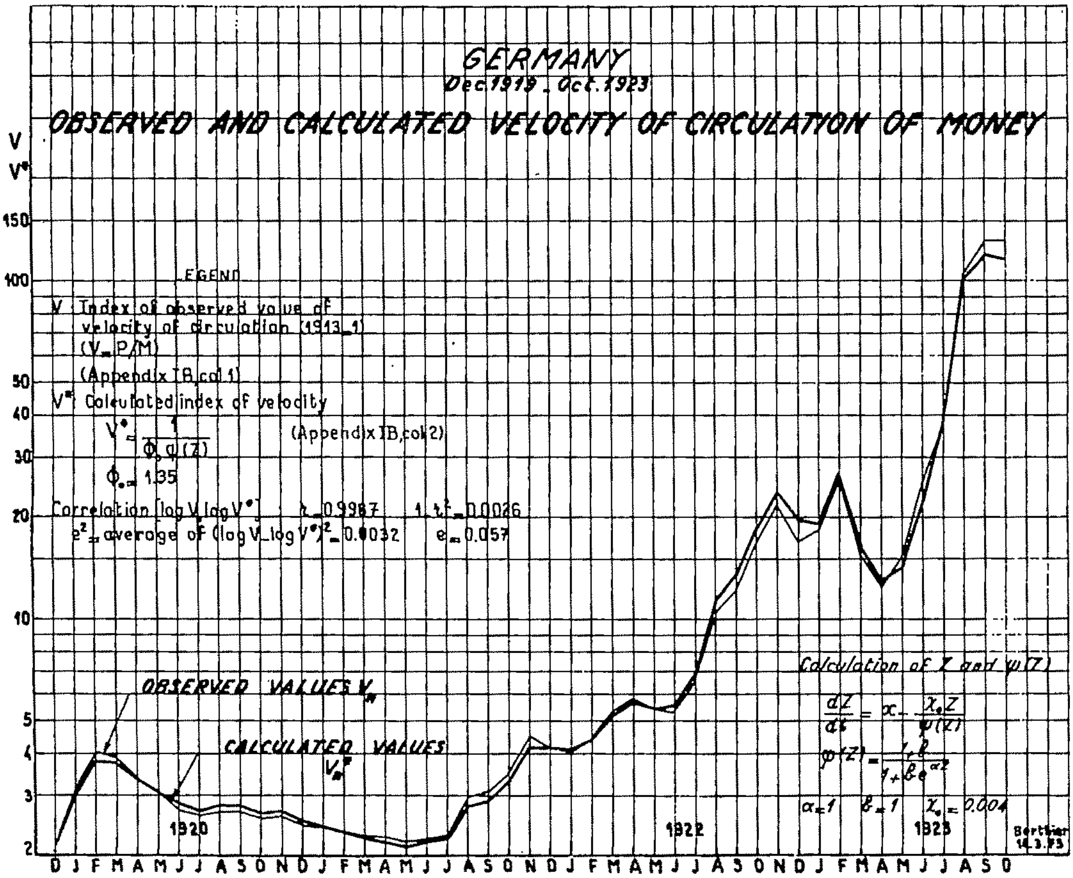

Figure 2

exposition is without foundation.[6]

2) *Unjustified Neglect of Second-Order and Higher Terms.* Secondly, Scadding neglects all second-order terms. As a general rule, such approximation is unacceptable. In fact $v^* = [(1+e^Z)/2]-1 = (Z/2)[1+(Z/2)+(Z^2/6)+\ldots]$ whereas Scadding takes $v^* \sim Z/2$. The relative error affecting v^* by limiting oneself to first-order approximation is shown in Table 1. Thus the relative error ranges from values of 29.7 percent to over 37,150 percent as Z varies from 0.5 to 8.

In fact, Z varies from -0.10 to 1.13 for Chart I, and from 1.5 to 5.78 for Chart II. For Hungary (1945–46) it varies from 3.3 to 8.2. Thus it is clearly wrong to say that "Except in the extremes of hyperinflation the second and higher moments of v should be small enough that we can approximate . . . to a first-order term . . ." (p. 152). This one observation is enough on its own to refute Scadding's reasoning practically in totality, for the validity of estimates, neglecting second-order terms, governs the mathematical basis of his argument.[7] The

---

[6] The confusion between V and V^* (i.e., between M and $M^* = M_D$) is all the more unfortunate in that $M - M_D$ cannot be taken as equal to zero in any way (see my 1972 paper, note 34).

[7] If we write as Scadding does, $\epsilon = (dV^*/V^*)/(dz/z)$ $[z=0]$, and if we consider that $z = \chi_0 Z$ and $V^*/V_0^* = (1+e^Z)/2$, then $\epsilon = (dV^*/V^*)/(dZ/Z) = Ze^Z/(1+e^Z)$ and ϵ is zero for $z=0$. Contrary to Scadding's affirmation, moreover, ϵ is *not* the absolute value of the elasticity of the demand for money with respect to the rate of interest. *This value is unity.* (See my 1969 paper, p. 459, relation (63).)

TABLE 1

TABLE 2

		United States 1918–1941		Germany Dec. 1919–July 1923	
	Correlations	r	$1-r^2$	r	$1-r^2$
(1, 2)	$\log(V_n/V_{n-1})$, $\log(D_n/D_{n-1})$	0.937	0.123	0.824 (0.485)	0.321 (0.765)
(2, 3)	$\log(V_n^*/V_{n-1}^*)$, $\log(D_n/D_{n-1})$	0.969	0.060	0.837 (0.463)	0.300 (0.785)
(1, 3)	$\log(V_n/V_{n-1})$, $\log(V_n^*/V_{n-1}^*)$	0.966	0.068	0.985 (0.990)	0.031 (0.021)

large changes in Z show how large the variations are in the rate of forgetfulness $\chi=\chi_0(1+e^Z)/2$ and it is impossible, this being so, to consider it as a constant.

3) *Comparative Changes in Global Expenditure and the Velocity of Circulation.* To buttress his arguments, Scadding states: "Moreover the rates of change of nominal output are a relatively smooth series compared to the behavior of velocity" (p. 154). Charts III and IV show that in the case of the series for the United States 1918–41 and Germany 1919–23 used as illustration, *there is nothing of this sort:* the relative changes in x are of roughly the same order of magnitude as those of the derivative $d \log V/dt$.[8] Similar relationships are observed for the other series, whether they relate to current situations or hyperinflations. Correlations of this kind are very remarkable indeed. They must be explained. The hereditary relativistic theory does this perfectly. As a matter of fact, the same correlations are observed to hold more closely between the x and the estimated quantities $d \log V^*/dt$. The data shown in Table 2 are obtained for the United States 1918–41 and Germany, December 1919–July 1923. The figures in brackets for Germany relate to the whole period December 1919–October 1923.

Relation (6) shows that according to the hereditary and relativistic model, the rate of change x of global expenditure, is the sum of two terms, of which the first is proportional to $d \log V^*/dt$, the coefficient of proportionality declining from 2 to 1 as V^* rises from V_0^* to $+\infty$. *This fact makes it possible to explain the correlation observed between x and $d \log V/dt$, insofar as the difference between V and V^* remains small, and insofar as the second term does not take on exceptionally high values*, which it does in the case of Germany during the three final months, from August to October 1923. Because of this, the correlation coefficients for Germany for the whole period December 1919–December 1923 have been shown in brackets: for the last three months, the influence of the second term of the left-hand side of relation (6) is anything but negligible.

Using the subscripts 1, 2, and 3 to denote $\log(V_n/V_{n-1})$, $\log(D_n/D_{n-1})$, and $\log(V_n^*/V_{n-1}^*)$, respectively, the standard formula

$$r_{12.3} = (r_{12} - r_{13}r_{23})/\sqrt{(1 - r_{13}^2)(1 - r_{23}^2)}$$

yields values of $r_{12.3}$ for the United States of 0.0076 and for Germany of -0.0011 when applied to the coefficients of Table 2. This suggests the conclusion that the series behave *as if* the observed correlation between

---

[8] In Chart III, x and $d \log V/dt$ are plotted against identical scales. In Chart IV, the scale for x is double that for $d \log V/dt$.

log (V_n/V_{n-1}) and *log* (D_n/D_{n-1}) is entirely due to the correlations between *log* (V^*_n/V^*_{n-1}) and *log* (D_n/D_{n-1}) on the one hand, and *log* (V_n/V_{n-1}) and *log* (V^*_n/V^*_{n-1}), on the other. Since from relation (4)

$$(8) \qquad dZ/dt = (1 + e^{-Z}) d \log V^*/dt$$

the correlation between x and *log* (V^*_n/V^*_{n-1}) is mainly due to the strong correlation between x and dZ/dt, resulting from relation (3) and the very strong correlation between dZ/dt and $d \log V^*/dt$ resulting from relation (8). This correlation evidently becomes stronger still when Z takes on high values, as it does in hyperinflations. It follows that it is essential to take due account of the order of magnitude of the three quantities entering into relation (3).

From an economic standpoint, these results indicate that the hereditary relativistic theory does explain why fluctuations in global expenditure are *always* accompanied by changes in the same direction and of the same order of magnitude in the velocity of circulation. It can also be seen that, contrary to what Scadding seems to suggest, cyclical fluctuations are also to be observed in the German hyperinflation. Their period is much shorter, and their amplitude increases as the hyperinflation proceeds. This phenomenon is also to be observed for the other hyperinflations. It follows that the arguments put forward based on consideration of cyclical fluctuations *should equally apply* to the fluctuations observed during hyperinflations.

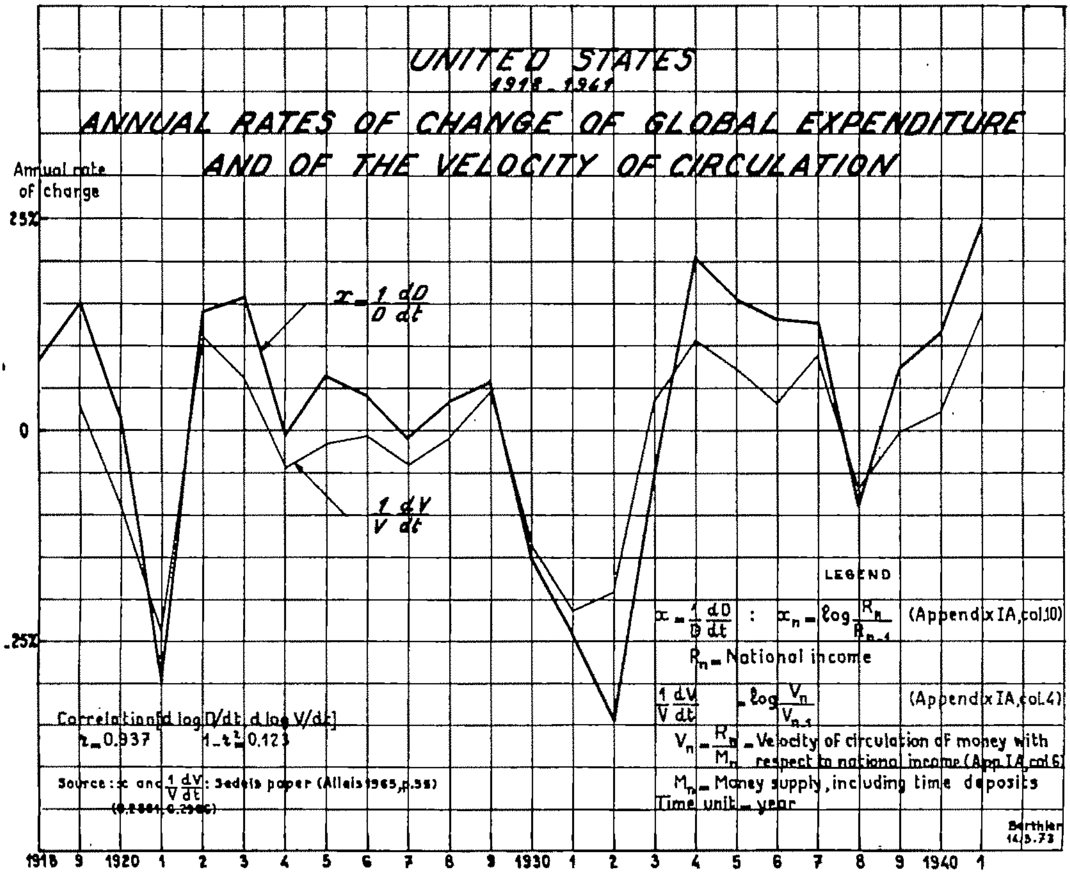

Figure 3

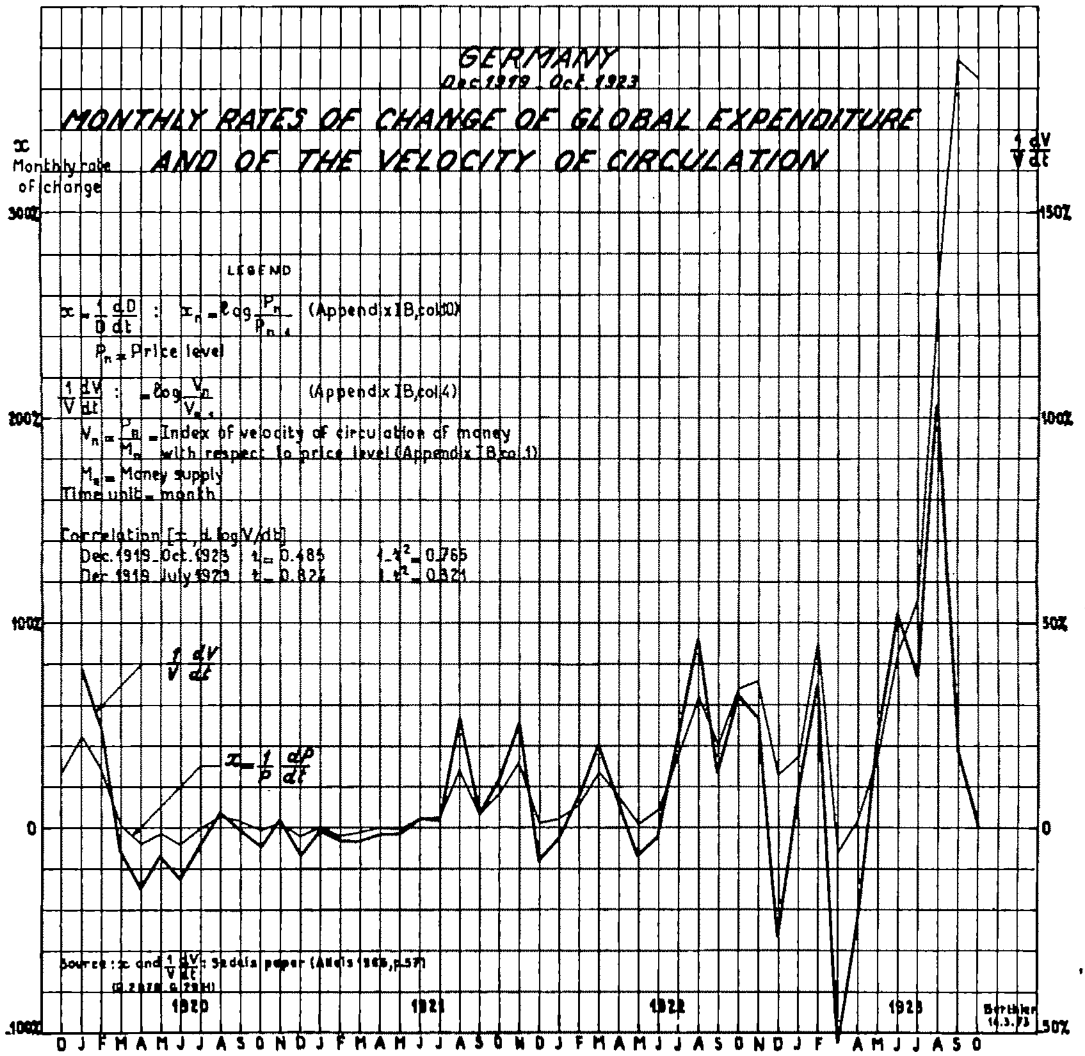

Figure 4

III. Circular Reasoning or Real Structural Relationship—Scadding's Paralogisms

In fact, Scadding's reasoning is founded on a series of paralogisms.[9]

1) *The Term in* z_1. Consider first Scadding's equation (19)

$$
(9)\quad v(t) = b_0 + b_1 z_1(t) - b_1\chi' \int_0^\infty x(t-s) \cdot \left\{ \sum_{n=1}^{N} D^{n-1}v(t-s)\frac{s^n}{n!}\exp\left[-\chi' s\right] \right\} ds
$$

He concludes from this that ". . . the Allais method of estimating velocity comes down to estimating it as a distributed lag in itself and its derivatives" (p. 153).[10,11] Even if this assertion is considered valid as regards the third term on the right-hand side of (9), *which it is not*,[12] it certainly cannot hold for the term in z_1 whose expression

---

[9] So confusedly interwoven are the factual errors and paralogisms in Scadding's paper that it is not easy to separate them out clearly.

[10] Equation (9) is written using Scadding's notation. In point of fact, the term b_0 should be considered as equal to zero (see fn. 11 below). Equation (9) is merely equation (7) above, ignoring second-order and higher terms in v^*, integrating $\int v^*(u)\,du$ by parts and replacing v^* by v. In other words, *if* v is entered in place of v^* in

$$(10)\quad z_1(t) = \chi' \int_{-\infty}^{t} x(\tau) \exp\left[-\chi'(t-\tau)\right] d\tau$$

is given by Scadding's relation (4).[13] Thus there is an error of reasoning here.[14]

No conclusion of any kind can be derived from the expression (9) in v if only the third term on the right-hand side is considered, and the second neglected. It can of course be argued that with x correlated with $d \log V/dt$, the quantity z_1 is itself a weighted average of past rates of change of the velocity of circulation. ***But in this sense, every argument brought forward against the hereditary and relativistic theory also holds against Cagan's theory.*** Be this as it may, the correlation between x and $d \log V/dt$ needs to be explained. It cannot be presupposed as a point of departure.[15] In fact, the "explanation" can be derived only from a model resting on certain assumptions. Why it comes about that such an explanation is possible, i.e., that such a model can actually be developed and verified, is of course a question that lies beyond the domain of science.

2) *The Arbitrary Identification of V and V* in the Reasoning, and its Implications.* The essential paralogism committed by Scadding rests on his arbitrary identification of V with V^* already noted (Section II.1) above). Its meaning and implications must be stressed as follows. Even if the approximations underlying equation (9) are valid, ***which they are not***,[16] equation (9) only applies for the quantity v^*, not for v. For Scadding's analysis to be correct, it would have to be true that $V \equiv V^*$. But this would be equivalent to supposing that the hereditary and relativistic theory represents the reality not only very well, but also perfectly.

In point of fact, Scadding's grounds for the charge of circularity derive only from an absolutely essential assumption which he does not state explicitly. This is that the hereditary and relativistic theory is valid. Obviously under this assumption the conclusion that there is circularity is a necessary corollary, since relation (9) is actually an identity once the relation $v \equiv v^*$ is accepted and second-order terms neglected. But this assumption cannot be accepted without ruining the foundation of all of Scadding's reasoning. Since the equality $V = V^*$, even if only approximate, is tantamount to assuming that two constants Z_1 and $V_0^* = 1/\phi_0$ can be found such that when (3) is integrated using observed values of x and an initial value Z_1 of Z, the values of V^* calculated using (4) will be close to the observed values of V.

In fact, whereas equation (9) with v^* in the first term in place of v follows ***necessarily*** (neglecting second-order terms) from the hereditary and relativistic formulation, there is no necessity at all for constants Z_1 and

---

equation (9) and *if* second-order and higher terms are neglected, this equation is an identity in v^*. In fact, Scadding's relations (10) and (11) are incorrect. The coefficient of the second term on the right is χ'^2 and not χ'.

[11] Scadding's relations (17) and (18) are incorrect. They should be read

$$v = (V - V_0)/V_0 = \{[1 + b \exp(\alpha z/\chi')]/(1+b)\} - 1$$

and, to a first-order approximation $v^* = b\alpha z/\chi'(1+b)$. It follows that, in Scadding's notation, in his equation (19), b_0 should be taken as zero.

[12] See Section III.2) below.

[13] z_1 is the value taken on by the product χZ when χ has the constant value χ_0, the coefficient Z being defined by relation (1) above.

[14] In any case, I do not see what value there is in reducing the hereditary and relativistic formulation to the Allais and Cagan formulation of 1953–54, which is now hopelessly out of date and irrelevant from any standpoint. In fact the real issue is not to try to link up the new formulation, which rests on a variable rate of forgetfulness, with the old one, which rests on a constant rate of forgetfulness. This link follows immediately and has no real interest. The real issue is to choose between the two formulations from an examination of the facts, and not from a priori reasoning.

[15] See Section II.3) above and Sections III.2) and III.3) below.

[16] It should further be recalled that equation (9) is wrong even for v^*, since it neglects second-order terms that cannot be neglected (see Section II.2) above). In reality, it is equation (6) above that should be used, not equation (9). I leave aside the obvious difficulties which arise from the consideration of higher order derivatives of v^*. From equation (6) above, this implies in particular the assumption that the various successive derivatives of $x(t)$ can effectively be considered.

ϕ_0 to exist such that there would be little difference between V and V^*. Alternatively, assuming that second-order terms can be ignored (which they cannot be), equation (9) (written with v^* in place of v) is an integral equation which defines v^* as an implicit function of the x. There is no a priori reason for a solution to be available in which the quantities v and v^* stay close to each other.

The value of the new theory and its empirical application lies precisely in the fact that it shows that such a solution exists, but this does not alter the fact that, a priori, there is no reason why it should. In fact, if $V \equiv V^*$ is assumed a priori, the result is mathematical circularity, whereas the purpose of the analysis is and must be to explain why V and V^* should be approximately equal.

To summarize, from the interdependence between x and V^* specified in relation (6), we cannot derive the conclusion that there is an equivalent interdependence between x and V, except if there is a close correspondence between V and V^*. This is an assumption that cannot be made a priori—without presupposing precisely that the hereditary and relativistic theory is valid. In reality, the implicit confusion of V with V^* has led Scadding to put forward a paralogism, and unfortunately, there is a some presumption that the reader would not perceive this unless forewarned.

3) *Absence of Real Justification for Scadding's Arguments.* Scadding's equation (19), given as equation (9) above, is derived from equation (7) above by replacing v^* by v, neglecting second-order terms and integrating $\int v du$ by parts. If this equation (7) is considered, there is no longer identity. As I have just shown, there is no a priori reason for the values of x estimated from (6) using the values of v instead of v^*, to be identical to the observed values.

To say that equation (9) above consists of regressing the index v on itself is not enough to explain the excellent results provided by the hereditary and relativistic theory, or for that matter, to prove anything at all. This is an affirmation where demonstration is called for. Scadding ought to show that the nature of the regression is such that the second term of equation (9) approximately reproduces the first. Examination of the results of contemporary research shows that lagged regressions do not necessarily always produce good results. When they do, there must be a particular structure which causes them, and it needs to be explained. This is exactly what the hereditary relativistic theory does in the present case.

Autoregression in itself does not guarantee a good fit. Scadding's thesis would mean that any variable whatever could be substituted for x as long as it is correlated with v and that any other function could be used instead of $\psi(Z)$ without any incidence on the good results obtained! For Scadding's reasoning to hold, this would require *either* a mathematical demonstration that the right-hand side of (9) does indeed reproduce the first, at least approximately, for any set of values of x, as long as they are correlated with v; *or* an illustration of his thesis by at least one specific example in which determinate functions are considered for v and x; or even a specific numerical example showing in a particular case that the reasoning presented is justified. The discussion in Section III.2) above shows clearly that this task is impossible. Otherwise, there would be a demonstration that the two sides of relation (6) where v^* is replaced by v necessarily differ little from one another. This is of course impossible unless one has postulated beforehand the complex and remarkable interdependence between the x and the V which the hereditary relativistic theory brings into the open. This postulate is implicit in Scadding's analysis. It follows that Scadding's thesis rests on circular reasoning, and that, for want of support, his thesis breaks down.

In any event, Scadding's arguments apply equally to Cagan's formulation (see Section III.1) above) once the correlation between x and $d \log V/dt$ is assumed a priori. But then what should be explained, and what Scadding does not explain at all, is the reason why one of two theories subjected to the same criticism (groundless in any case) produces markedly better results than the other. In other words, we should be told why consideration of the quantity Z, corresponding to relation (1), gives better results than consideration of z_1, corresponding to relation (10). In my view, the reason is that the hereditary formulation is closer to reality because it considers relative desired money balances M_D/D, instead of real desired money balances M_D/P; the rate of increase of global expenditure x instead of p, the rate of increase of prices; a logistic instead of an exponential function for M_D/D, and a variable rather than a constant rate of forgetfulness. Last but not least, relative desired money balances are assumed invariant when measured against a psychological time scale. It follows that the currently accepted models of the demand for money (whether based on Philip Cagan's rate of anticipation, Milton Friedman's permanent income, or the rate of interest) are all misspecified.

4) *The Correlation between the Rate of Change of Global Expenditure and of the Velocity of Circulation.* Scadding writes: "Since the short-run behavior of velocity is pro-cyclical, the rates of change of nominal output and velocity are positively correlated. Hence the configuration of x-weights will tend to preserve the past variation in velocity," and, a little earlier, "In other words, the sum of terms representing the difference between the Allais and Cagan estimates is a series expansion in v, not x" (p. 154).[17] This leads him to conclude that "For all these reasons, the Allais procedure is approximately that of regressing velocity on a smoothed version of itself" (p. 154).

In the first place, a correlation between x and $d\ log\ V/dt$ does exist, as can be seen from Charts III and IV above for the United States, 1918–41, and Germany, December 1919–October 1923. The correlation coefficients are, respectively, 0.936 ($1-r^2=0.123$) and 0.485 ($1-r^2=0.765$), whereas the correlation coefficients between $log\ V$ and $log\ V^*$ are 0.991 ($1-r^2=0.018$) and 0.998 ($1-r^2=0.0039$), as shown in Charts I and II above. But this makes it somewhat difficult to explain the correlation observed between $log\ V$ and $log\ V^*$ (Charts I and II) as being due to the correlation between x and $d\ log\ V/dt$ (Charts III and IV). In fact, the opposite is true. The correlation between x and $d\ log\ V/dt$ is in reality no more than the consequence in a particular case of the structure of the model represented by equation (6).

Actually, of course, there is no reason for this to be so a priori. As I noted earlier, it is remarkable that the correlation between x and $d\ log\ V/dt$ should not only be found for current situations (what Scadding calls "cyclical"), but also for all the hyperinflations studied. This results from equation (6) above, which shows that the first element of x is proportional to $d\ log\ V/dt$. Thus the hereditary and relativistic theory provides an explanation of this very remarkable fact.

Secondly, it is a paralogism to conclude from the cyclical structure of the time-series that the hereditary and relativistic formulation is tantamount to regressing velocity on itself. The whole point is precisely to determine explicitly the conditions that make this so, and in fact these conditions correspond to a specific structure of the economy which the new theory brings into the open.

Thirdly, Scadding's reasoning *completely* ignores the essential fact that the hereditary and relativistic theory applies equally to the full span of hyperinflationary periods and to current situations. Any attempt to question the economic significance of the new theory should therefore be applicable without modification to hyperinflations. Actually, the remarkably good results yielded by the hereditary and relativistic theory when applied both to hyperinflations and current situations is a fundamental aspect of it which the critics have neglected in a manner which is quite difficult to explain. This in turn suggests that the models used hitherto are misspecified since they are incapable of explaining the complex interdependence of the money supply and global expenditure time-series which is put in evidence by the hereditary and relativistic theory, while at least some of the results (which in any case are not very good) of the currently used models are probably the fruit of spurious correlations.

---

[17] For Scadding's reasoning to hold, this proposition should also apply to Cagan's estimate z_1 (see Section III.1) above).

Scadding also writes: "The fact that extrapolation of time-series often give good predictions may be enough to explain the good results that Allais obtains" (p. 151). It is hard to see how the—not particularly regular—success of extrapolations on short periods can provide any explanation of the success with which fittings were obtained covering normal situations lasting over long periods of years as well as the full duration of a series of hyperinflations. This is yet another claim that is unsupported by any effective proof.

5) *The Choice between the Rate of Change of Global Expenditure and of Prices.* Scadding asserts that no significance attaches to the choice of the rate of increase of global expenditure rather than the rate of price increase p. There is no basis for this assertion, which comes down to saying that if Z is defined by the relation $V/V_0=(1+e^{\alpha Z})/2$, the verification of equation (3) is not affected if x is replaced by p, or in other words that it is always possible to find a value of ϕ_0 such that the fit is equally good whether x or p is taken. This is a wholly gratuitous affirmation, and in fact it is invalidated by calculations undertaken on an alternative basis.

6) *The Use of the Fourier Transform.* Finally, Scadding puts forward an argument in which, assuming that the derivatives of x are bounded, he deduces the existence of an underlying identity, and so is not surprised that ". . . the Allais estimates are very good approximations" (p. 154, fn. 5). This simple assumption, for which no justification whatever is presented,[18] is the starting point for a chain of reasoning based on the Fourier transform which is, to say the least, dubious if not incomprehensible[19] and attempts to cast doubt on the economic meaning of the hereditary and relativistic theory.

---

[18] There is no evidence that the successive derivatives of x for the series United States 1918–41 remain bounded; rather the opposite is true.

[19] I have read and reread Scadding's fn. 5, and consulted pages 32–34 of Papoulis' work to which he refers. Leaving aside the fact that the reference to relation (15) is erroneous and should no doubt be to relation (5) of his text, I cannot see how the properties of the Fourier transform can apply to z. Perhaps Scadding might feel called upon to have a detailed and convincing note on this question published in the *Review*. I have my doubts that he can, for the proposition he tries to demonstrate is really undemonstrable unless the hypothesis is made first that $V=V^*$, which precisely presupposes the validity of the hereditary and relativistic theory (see Section III.2) and III.3) above). In fact, this assumption, which is necessary for his reasoning to be consistent, has nothing to do with the Fourier transform.

Professor Allais' Theory of the Demand for Money: Rejoinder

By JOHN L. SCADDING*

I find myself in a situation like that of Moliere's M. Jourdain who was surprised to learn that he spoke prose. I am surprised to learn that—according to Maurice Allais, at least—I commit paralogisms.

If all I wanted to do was dispute that, I would not take up space with this rejoinder; the law of diminishing returns applies with special force to these running controversies. The problem is, however, that Allais does not address himself directly to my criticism, and I think the criticism is important because it is fundamental.

My point was a methodological one: that the tests of Allais' theory are probably quite weak. Allais' skirting of this point is unfortunate for two reasons. The first is that one might get the idea, from reading his reply, that his hereditary and relativistic formulation of the demand for money was under attack. The second is that one might think that he provides confirmation of his theory when I think that a careful scrutiny of his test procedures suggests otherwise.

On the first point, nothing was further from my mind when I wrote my comment than an attack on the *ideas* in the hereditary and relativistic formulation of the demand for money. Quite the opposite was the case. I had then, and I continue to have, nothing but admiration for Allais' theory, which I think is original and may ultimately prove fruitful.

I addressed myself only to the second point. The nub of the problem is that, in going from theoretical to empirical specification, Allais introduced an approximation which very likely robbed his tests of much power. That approximation consists of using velocity as a measure of the rate of forgetfulness (1966, p. 1135, equations (2.38) and (2.41)). That means that the estimated coefficient of psychological expansion[1] is a function, among other things, of past velocity. Since that coefficient is used to predict velocity, Allais' testing comes down to estimating velocity as function of its past. It could come perilously close, in other words, to estimating velocity as an autoregressive process. And if that is true, the test of the structural content of the theory is minimal.

Allais' characterization of the above argument is that I accuse him of circularity. That is simply not true. What I suggest is that his tests have little power against the naive alternative of an autoregressive specification for velocity. It may be that velocity *is* a good measure of the rate of forgetfulness. But I have serious doubts as to whether we are going to be able to test that—or the other parts of the theory—by appealing to the behavior of velocity.

Allais in fact concedes that his test must be weak, although he does not say so explicitly. He grants that my argument is correct if we can identify measured with desired velocity (what he calls observed and estimated velocity): "... Scadding unfortunately fails to make the distinction between the observed and estimated values V and V^*. In fact, his mathematical reasonings are valid *only if* V *and* v *are replaced therein by* V^* *and* v^*" (p. 456).

Yet in his original paper, Allais makes the same assumption in deriving the empirical form of his hypothesis: "... but it can reasonably be suggested that the discrepancy between the actual and the desired value of money holdings is always relatively small. ... It further follows that it is possible to write as a first approximation ... (3.2) ... (3.3) $\phi_D \approx \phi$ ... " (1966, p. 1138).

---

* Stanford University.

[1] The analogue, say, of Cagan's anticipated rate of inflation. I use the word analogue because Allais takes exception to thinking of his psychological variables as in any sense anticipated or expected variables.

But ϕ_D and ϕ are the inverses of V^* and V. Allais therefore assumes for empirical testing that V^* and V *are* the same. And he concedes that my analysis is correct under those circumstances. So as far as I can see, we are in complete agreement.

Required Disclosure and the Stock Market: Comment

By IRWIN FRIEND AND RANDOLPH WESTERFIELD*

In his recent article in this *Review*, George Benston concludes that empirical analysis provides no support for the belief that the disclosure and related provisions of the Securities and Exchange Act of 1934 were either needed or desirable. Since Benston considers disclosure the basic reason for enactment of the 1934 Act, he is highly dubious about the usefulness of this legislation. We shall indicate that the conclusions he draws from his analysis seem faulty.

It should be pointed out at the outset that Benston covers only the Securities and Exchange Act of 1934 and not the Securities Act of 1933. At times, however, his conclusions do not seem to be limited solely to the particular disclosure requirements of the 1934 Act, but instead pertain to both acts. For example, the last sentence in his paper states, "Certainly there is doubt that more required disclosure is warranted" (p. 153), which does not necessarily follow from his previous conclusion that the 1934 Act had no effect on outstanding issues traded on the New York Stock Exchange (*NYSE*).

It is important to note, therefore, that while disclosure is the central feature of 1933 Act, it is only one, though an important, feature of the 1934 Act. Since the increase in disclosure effected by 1933 Act is very much greater than that effected by the 1934 Act, we think that the new issues evidence of the 1933 Act is highly relevant to the likely impact of the disclosure requirements in the 1934 Act. Thus both the 1933 Act and the 1934 Act must be included for a prudent assessment of the efficacy of disclosure requirements. We interpret the evidence on the 1933 Act as clearly favorable to disclosure.[1]

Our own interpretation of the evidence other than Benston's directly relevant to the evaluation of the 1934 Act is that it supplies some support to the thesis that this legislation may have improved efficiency in the market for outstanding stock, but that the evidence here is not so strong as for new issues (see Friend (1972), (1969)). The rest of this comment will examine the new evidence developed by Benston to analyze the impact of the 1934 Act disclosure, with special reference to his two major sets of tests.

I. Impact of Changes in Accounting Data on Common Stock Prices

The first of these tests, which was presented at greater length in earlier studies (see Benston (1967), (1969a)), estimates cross-sectional regressions in the year 1964 between changes in prices of individual stocks on the New York Stock Exchange (adjusted for movements in the market) and "unexpected" changes in each of a number of different financial variables (net sales, cash flow, net operating income, and adjusted net income), with changes in dividends and industry dummies included in all of these relationships. Expected changes in these financial variables were derived from several simple autoregressive models based on past data and then compared with subsequent published data to obtain estimates of unexpected changes. A similar but more limited analysis was carried out for 1963.

For reasons which are obscure, Benston does not use more than one of these unexpected changes in financial variables in the same regression, but only one at a time. Even so, his findings suggest statistically significant relations between price changes and the unexpected changes in each of these financial variables. Nevertheless, in view of what he considers the small size of the regression coefficients, he concludes that ". . . this evidence is not consistent with the underlying assumption . . . that the financial data made public are timely or relevant, on average" (p. 139).[2] There does not seem to be any justification for his willingness to dismiss out of hand the economic importance of these statistically significant results. Thus, he in effect considers not too relevant for stock prices knowledge about changes in financial variables, in spite of the fact that he finds an increase of 100 percent in the annual rate of net sales is associated with an increase in price of 10.4 percent in the month of the announcement, and that changes in other variables are also associated with significant though proportionally smaller changes in price.[3]

---

* Professor of finance and associate professor of finance, respectively, University of Pennsylvania.

[1] In addition to the papers cited by Benston, see also Friend and Edward Herman.

Moreover, it seems clear that Benston's regressions considerably understate the usefulness of published financial statements. They do not allow for the joint effects of unexpected changes in the different financial variables, and they make no adjustment for the substantial understatement of the relevant regression coefficients arising from the very large random measurement errors associated with any empirical measures of unexpected change.[4]

II. Effects of Disclosure on Expected Return and Risk

Benston's second set of tests, presented for the first time in his 1973 paper, is intended to determine whether stocks which were affected by disclosure provisions of the 1934 Act behaved "better" relative to the market as a whole than stocks for which disclosure was already available prior to the Act. For purposes of these tests, he classifies 508 *NYSE* stocks in the predisclosure period into two groups, one consisting of 193 stocks which did not disclose their sales versus 314 which did. Benston uses his earlier study to justify the selection of sales, maintaining it indicates that sales was the only relatively important accounting number. However, net income would seem to be the more theoretically relevant variable and in fact is the more consistently significant in its effect on price according to his earlier test ((1967), (1969a)), even though the estimated elasticity of price with respect to income was considerably smaller than with respect to sales.

It is interesting therefore that (with one possible exception) all of the 193 stocks which did not disclose sales did disclose net income as well as balance sheet and other financial data, so that Benston's second set of tests does not distinguish between nondisclosure and disclosure firms but between less and more disclosure firms that trade on the New York Stock Exchange. Moreover, this type of test tells us nothing about the relative quality of disclosure for both groups of firms before and after the 1934 Act, so that with relatively moderate differences in the quantity of financial data disclosed for these two groups, changes in the quality of disclosure which are likely to affect both disclosure and nondisclosure firms similarly may well be much more important.

To distinguish between the relative performance of nondisclosure and disclosure firms after the 1934 Act, Benston estimates *beta* coefficients, residuals from the market model, and the variance of these residuals for individual stocks in both groups of firms before and after the Act.[5] There is no evidence from the *beta* coefficients that the nondisclosure firms were adjudged relatively less risky in the post-Securities and Exchange Commission (*SEC*) period.[6] This is the only substantive evidence supporting Benston's position. However, even this evidence seems weak to us, because of the question of the difference between the two groups in the degree of nondisclosure. Moreover, there are several external studies showing that current accounting data can be used to make at least as good and possibly superior forecasts of future asset risk (as measured by *beta*) than forecasts dependent only on historically estimated asset risks (see William Beaver, Paul Kettler and Myron Scholes, and Richardson Pettit and Westerfield (1972)).[7] The accounting data which turn out to be useful for this purpose are balance sheet and income account items other than sales.

---

[2] Benston alleges that almost all previous empirical work relating published accounting data to stock price changes leads to the conclusion that the data are not useful or are redundant. However, our limited survey of several recent articles indicates many writers have concluded that published accounting profile variables can be useful in making investment decisions and contribute to market efficiency. See Alvin Martin and Robert May.

[3] Benston does not present a model or a theory that establishes explicit expected values for the regression coefficients in his equation. He states in the preceding article, "If a corporation's financial statements contain unanticipated information, the expectations of the investor about present value of the corporation should change" (1969a, p. 32). Hence, to conclude that disclosure legislation is largely useless because stock prices are not "strongly" affected, especially after statistically significant results are found, seems unwarranted. It puts too heavy a reliance on the intuitive beliefs of the researcher.

[4] The bias introduced from measurement error can be quite large. A discussion of the sources of measurement error when utilizing accounting data is found in William Beaver, Paul Kettler, and Myron Scholes, p. 670–72, which proposes a regrouping procedure to reduce the measurement error. A similar study by Richardson Pettit and Westerfield (1972), e.g., Table 2, pp. 1659–60, indicated that measurement error accounted for 50 to 90 percent of the total variability in the dependent and independent variables in a multivariate regression model. Thus, the estimates of the regression coefficients associated with empirical measures of unexpected changes will probably greatly understate the true values.

Before leaving this discussion of the impact of the 1934 Act on stock *betas*, we should point out that of the three ways the Act might be expected to affect the level and variability of stock prices—through effects on expected return, *beta* coefficients, and residual variability—*beta* coefficients, which measure the covariability of returns on a stock with those on the market, would be expected to be affected least. We have indicated that Benston's analysis suggests that the 1934 Act did improve estimates of expected return. We turn now to its apparent impact on residual variability.

The residuals from the market model in this second set of tests, derived from regressions for each stock fitted to the entire pre-*SEC* and post-*SEC* periods covered, seem to indicate that both disclosure and nondisclosure firms performed better in the post-*SEC* than in the pre-*SEC* periods in the sense that residual risks were reduced for both groups of firms. The algebraic and absolute means of these residuals were computed for disclosure and nondisclosure firms separately for each of four pre-*SEC* periods, for an "adjustment period" (representing the estimated time between congressional action on the bill and "full compliance"), and for three post-*SEC* periods. The absolute means of these residuals, which seem more meaningful than the algebraic means,[8] exhibit a steady increase throughout the pre-*SEC* periods both for disclosure and nondisclosure firms, turn downward in the adjustment period and then continue at the lower level thereafter, with a lower absolute mean in the post-*SEC* than in the pre-*SEC* period.[9]

---

[5] For a recent discussion of the theoretical and empirical properties of the market model, see Marshall Blume.

[6] It should be noted that Benston assumes that an estimate of the *beta* coefficient provides a good measure of the risk of an asset. For this assumption he repeats the "portfolio approach" justification for the *beta* coefficient (see Blume). Contrary to Benston's assertions, none of the assumptions that the portfolio approach depends upon appears strictly correct, and empirical evidence on the validity of the *beta* coefficient is not conclusive. Therefore, it might have been illuminating to have included total variability estimates to supplement the analysis. This is especially true when dealing with individual securities (see Merton Miller and Scholes).

[7] Still another technical problem with Benston's analysis is that he does not indicate how his *beta* coefficients were estimated. We would surmise that he does not adjust for bias in estimating *beta* from contemporaneous data on rates of return on the individual stocks and on the market, and that he implicitly assumes that the universe rate of return on the minimum variance zero *beta* asset is constant over each of the periods covered—in one case the pre-*SEC* and post-*SEC* periods separately, in another the entire period as a whole.

[8] Benston appears mistakenly to consider the sign of the average residual in any time period as a measure of stock performance. He seems to confuse a positive residual with a positive constant term, α_i, in the capital asset pricing line $R_{it}=\alpha_i+R_{0t}(1-\beta_i)+\beta_i R_{mt}+\delta_{it}$, where R_{it} is the one-period return relative of the ith asset, R_{mt} is the one-period return relative of the market portfolio, and R_{0t} is the return relative on a "zero *beta*" asset. The error term δ_{it} is assumed to be independently distributed. The residual terms δ_{it} can be used to measure relative performance only if the intercept terms α_i and the measurement errors in β_i are the same for both sets of firms before and after the disclosure period. Moreover, using the residuals terms to measure relative performance is not strictly compatible with their required properties in estimating the market model.

[9] The absolute means suggest that Benston is mistaken in the first of his two "basic" conclusions that he draws from these data, viz., that " . . . there appears to be somewhat less variance of the residuals of both groups during . . . the adjustment period . . . compared to the following and preceding months" (p. 146).

The pattern of the algebraic means is also revealing. In the four periods before the transition period there is no significant difference between disclosure and nondisclosure firms, although in each period the difference is negative. However, in the first period after the transition period, July 1935–June 1937, the difference between the algebraic means of the residual terms for the disclosure and nondisclosure firms becomes positive and is greater than the differences observed in the other periods.[10] In the subsequent two periods the residuals become negative. Thus, in only one period are the differences in residuals positive. Moreover, this difference appears in the first period after the disclosure legislation (which is the critical period if adjustments and revaluations take place quickly) and does not support Benston's conclusion that the 1934 Act had no effect on stock market prices. In contrast, the results tend to support the hypothesis that managers avoided disclosure to hide their poor performance. The mean of the standard deviations of residuals is also lower in the post-*SEC* period for both groups of firms.

Thus Benston's conclusion that ". . . the '34 Act did not contribute to a reduction in the variance of returns . . . as measured by . . . the standard deviations of the residual returns on securities . . ." (p. 149) may be questioned from his own results (see Table 4, p. 149). It may also be questioned on the basis of a more comprehensive analysis carried out elsewhere (Friend (1972)) which regresses on time the standard deviation of residuals (of the capital asset pricing line) from a series of cross-section relationships of portfolio monthly return and risk for twenty-one periods of twenty-four months each from July 1926 through June 1968. This study finds a statistically significant downward time trend in these residuals. This analysis avoids many of the problems affecting the Benston analysis.

III. Other Analyses

With respect to other arguments Benston makes, he asserts in his Summary and Conclusions: first, that ". . . the effect of the '34 Act on the capital market may have been perverse, since the percentage of corporate expenditures on plant and equipment financed with new public stock and debt issues was lower in the post- than in the pre-*SEC* decades" and second, "With respect to fairness, the evidence that the disclosure requirements did not result in a revaluation of the securities of the affected firms and the conformity of price changes before 1934 to a random walk indicates that the pre-*SEC* stock market was a fair game for investors" (p. 153). So far as the percentage of capital expenditures financed with new issues is concerned, it is not at all clear where Benston draws the justification for his conclusion. The data he presents show that new issues account for a higher proportion of capital expenditures net of depreciation (presumably the only relevant comparison) in 1949–54, the last period he covers, than the corresponding proportion for 1900–24. It is only in the 1920's that a higher ratio is observed, and the size of that ratio (354 percent) might suggest an excessive use of the securities markets in the 1920's or a mistake in arithmetic. Moreover, Benston does not point out as he does in an earlier article (1969b) that the very much higher rate of personal income taxes (relative to capital gains taxes) might be expected to bring about an increase in internal financing in the post-*SEC* period.[11]

---

[10] The student *t*-value for this difference is approximately 1.003 which is clearly not significant under the usual assumptions but is greater in absolute value than the other periods (excepting the transition period).

[11] Another Benston finding that the ranking of industries by the percentage of private placements to total debt issues (which he considers an indication of *SEC*-induced inefficiencies) ". . . was almost exactly the same as a ranking of the extent of bias of the *SEC*'s conservative accounting rules . . ." (p. 151) appears impressive mainly because of the electric and gas, communication, and railroad industries, which have relatively unique methods of debt financing. Another problem with Benston's analysis is the omission of leasing, which can be interpreted as a form of private placement. Railroads are particularly fond of this method of financing. Furthermore, it should be noted that the importance of private placements has markedly decreased since the end of Benston's time period (i.e., 1966).

Benston's last argument relating to the impact of the 1934 Act on fairness is similarly flawed because he draws no distinction between efficiency and fairness in the stock market. While his definition of fairness (p. 152) is not clear, it would appear from his reference to Eugene Fama's "semi-strong form of the martingale hypothesis" (p. 152) that Benston considers a market fair in which corporate insiders make large profits at the expense of other investors so long as this is accomplished quickly.

In fact, none of his tests is relevant to the fairness of the market as between corporate or market insiders and public investors. Yet corporate investors who have access to inside corporate information and stock exchange specialists who have access to inside market data are the only two groups in the market who apparently receive above average returns in the market (see Friend and John de Cani, and Fama). It is our strong impression, based on a reading of congressional reports, scholarly studies, newspaper articles, and many discussions with professionals in the market, that the ability to take advantage of inside information and the relative profitability of corporate insiders and specialists in the pre-*SEC* period were much greater than in the post-*SEC* period.[12] Clearly this would not be reflected in Benston's analysis, which does not distinguish between the experience of insiders and outsiders.

Benston's analysis is relevant (though deficient) to whether disclosure improved certain types of market efficiency, but not to whether disclosure improved fairness as between insiders and the public. This statement applies not only to his specific tests of the impact of disclosure provisions but also to his random walk tests in the pre-*SEC* and post-*SEC* periods. Two further comments on his random walk tests may be in order.

First, random walk tests which examine the degree of serial independence in security returns, such as the runs tests used by Benston, test only the nature of the market reaction to a given set of information or misinformation and do not test for other aspects of market efficiency, namely, the quality and quantity of information produced in the market (see Friend (1972)). Second, a more important market inefficiency occurs when two portfolios of the same risk realize substantially different returns. In a recent paper (Blume and Friend), it was found that in the pre-*SEC* period tested (1928–33) a monthly rebalancing investment strategy applied to a portfolio of *NYSE* stocks (i.e., maintaining initial portfolio weights by buying stocks which declined in price and selling those which rose) yielded very much better, though from a statistical viewpoint not necessarily significantly different, results than a buy and hold policy.[13] This was not true in the post-*SEC* period as a whole. One of several explanations for these results would be an increase in market efficiency from the pre-*SEC* period to the post-*SEC* period due to securities legislation. We feel such a comparison provides a more relevant test of market efficiency than the runs tests used by Benston.

---

[12] For example, see the reports of the *Federal Trade Commission, Securities and Exchange Commission, Special Study of the Securities Markets* and the Senate hearings on *Stock Exchange Practices*.

[13] This was true even after allowance for differential taxes, commissions, and risk.

Required Disclosure and the Stock Market: Rejoinder

By George J. Benston*

Irwin Friend and Randolph Westerfield's (F-W) comment on my article is appreciated. It certainly is desirable that generally respected legislation, such as the Securities Exchange Act of 1934, be subjected to scientific analysis and that the analysis be subjected to criticism. I shall reply in this rejoinder, item by item, to the critique presented by F-W. For the reader's convenience, the order of their presentation is followed and the most succinct expression of their criticism, wherever possible, is quoted for reference.

1. "We interpret the evidence on the 1933 Act as clearly favorable to disclosure." Since I did not analyze the 1933 Act, the "evidence" does not refer to my paper. Rather their reference is to George Stigler's pioneering analysis as corrected by Friend and Edward Herman (1964, 1965). The data presented in these papers indicate an insignificant difference in the mean rate of return (relative to the market) on stocks floated in the years 1923–27 compared to flotations in the period 1949–55. However, the standard deviations of the returns are higher in the pre-Securities and Exchange Commission (*SEC*) period, which F-W assume is "favorable." Assuming that these findings from an admittedly crude and not well specified "model" can be taken as valid, greater variance of a subset of assets (new issues) should not be considered favorable or unfavorable without consideration of portfolio effects. A constraint by the *SEC* on the availability of assets with a greater variance of returns may prevent investors from constructing portfolios consistent with their preferences for return and risk. Without knowledge of the covariance of returns among securities and other assets and of the effectiveness of the *SEC*, relative to private individuals, in measuring potential risk and in screening out fraudulent issues, one should not ". . . interpret the evidence as *clearly* favorable to disclosure" (emphasis added).

2. ". . . Benston does not use more than one of these unexpected changes in financial variables in the same regression. . . ." This criticism to an earlier, summarized study is correct (though unexpected changes in dividends, quarterly earnings and industry dummy variables were included). However, Nicholas Gonedes (1973) recently completed a similar study which used seven accounting data ratios simultaneously (combined with multiple discriminant analysis into an index): he reports results similar to those of my study.

3. ". . . many writers have concluded that published accounting profile variables can be useful in making investment decisions and contribute to market efficiency" (fn. 2). No such conclusions are drawn in the articles they cite. May (cited in F-W) simply reports a greater than usual variance of price changes in the weeks around the dates when quarterly earnings are announced. He did not posit the conclusion stated by F-W. Martin (cited in F-W) regressed changes in share prices over the period contemporaneous with or prior to the time the accounting statements were published. His study suffers from serious conceptual and statistical problems, which are detailed in the comments published with the article. Moreover, other studies, in addition to those cited in my article, which show no economically significant predictive effect of published accounting data on share prices include Phillip Brown, Gonedes (1971), and William Beaver and Roland Dukes. I will again emphasize here, as I did in my paper, that an economically significant relationship between share

---

* Professor, Graduate School of Management and Center for Research in Government Policy and Business, University of Rochester.

prices (or some other variable) and published financial statements is necessary but not sufficient support for the hypothesis that mandated disclosure is beneficial in some way.

4. "Benston does not present a model or theory that establishes explicit expected values for the regression coefficients in his equation" (fn. 3). The model was presented on pages 3–5 of my 1967 paper (cited by F-W). A similar model (or rationale) is presented in much greater detail in Gonedes (1971) and briefly in Richardson Pettit and Westerfield, p. 1652 (cited in F-W). The signs of the coefficients, though not the magnitudes, are specified or implied in the models described in these papers. It is true, though, that the models do not establish criteria for determining whether a 2 percent change in share price returns coincident with a 100 percent change in the rate of change of reported net income is meaningful or not.

5. ". . . substantial understatement of the relevant regression coefficients arising from the very large random measurement errors. . . ." F-W cite studies which use a *beta* grouping technique to reduce such errors. Gonedes (1973), who used this technique, reports results similar to mine. Further, Westerfield should reread his own statement concerning measurement errors given by Pettit and himself that ". . . errors in measurement of earnings—due in part to accounting inaccuracies— . . . [are] only approximations for the underlying 'true' values" (p. 1660). Given their conclusion, they should question why the *SEC* has done so little to reduce these errors, or even to provide investors with some indication of their magnitude and effect.

6. ". . . net income would seem to be the more theoretically relevant variable [than sales]. . . ." It should be noted that virtually all companies who were affected by the 1934 Act reported net income. Sales was the principal important datum not generally disclosed before the Act and therefore whose disclosure was mandated, de facto, by the Act.

7. ". . . changes in the quality of disclosure which are likely to affect both disclosure and nondisclosure firms similarly may well be much more important." Granted. Unfortunately, neither F-W nor anyone else, to my knowledge, has defined "quality of disclosure" operationally or offered any evidence of greater quality after than before passage of the 1934 Act.

8. ". . . none of the assumptions that the portfolio approach depends on appears strictly correct, and empirical evidence on the validity of the *beta* coefficient is not conclusive. Therefore . . . total variability estimates [should have been included]" (fn. 6). Since assumptions never can be "strictly correct" and empirical evidence can never be "conclusive," I am at a loss to understand the first sentence. With respect to the second sentence, F-W's comment is, I believe, based on the Douglas-Lintner results, given in George Douglas, which report a significant relationship between *ex post* average returns on stocks and the residual variance, rather than total variance. Merton Miller and Myron Scholes (cited by F-W) examined the validity of this result and demonstrated that it could result simply from skewness in the return distributions of the annual data used by Douglas. Michael Jensen and Eugene Fama and James MacBeth also considered this question. Both papers report a substantial relationship between the *ex post* average returns on securities and the systematic risk measured by *beta*. However, they found that the residual variance is not importantly related to the average *ex post* returns of securities over and above that which is already explained by the *beta* coefficients. Jensen concludes: "Thus while the variable may be statistically significant, its *economic* significance is virtually nil . . ." (in footnote 35, p. 367); Fama and MacBeth conclude: "We also cannot reject the hypothesis of the two-parameter model that no measure of risk, in addition to portfolio risk [*beta*], systematically affects average returns" (p. 633). The implication of these studies is that, having considered the *betas*, inclusion of total variability would not "have been illuminating" as F-W assert.

9. "... several external studies showing that current accounting data can be used to make at least as good and possibly superior forecasts of future asset risk...." The Pettit and Westerfield study referred to uses contemporaneous accounting and market data: hence it is irrelevant. The other study referenced to support the quotation, by William Beaver, Paul Kettler, and Scholes, uses accounting data from one decade (1947–56) as instrumental variables to estimate the *betas* of individual securities and portfolios. The accounting data provided very slight improvement in predicting *betas* in the next decade (1957–65) over the naive model (one decade's *beta* is the same as the preceding decade's *beta*) for individual securities and somewhat greater improvement for portfolios. However the magnitude and economic import of the improvement is not given. Gonedes (1973) presents (and I believe better specifies) tests in which he finds statistically significant, but low correlation coefficients (the highest is .45) between market and accounting based estimates of systematic risk. He supposes that the Beaver, Kettler, and Scholes results "... are actually functions of market prices because they used market prices to scale income numbers. Hence, their results may simply reflect 'spurious correlation'" (p. 43). F-W thus somewhat overstate the reported usefulness of accounting data for forecasting *betas*.

10. Benston "... does not indicate how his *beta* coefficients were estimated" (fn. 7). Not so. See pages 142–43. The adjustment period was excluded from the data used to calculate the *betas*. While it may have been preferable to use a portfolio approach to estimate *betas*, the procedure used of comparing disclosure with nondisclosure companies over the same time periods adjusts for "contemporaneous data on rates of return on the individual stocks and on the market" which F-W wish. (These comments also answer fn. 8.)

11. "We have indicated that Benston's analysis suggests that the 1934 Act did improve estimates of expected return." I have been unable to detect where in their comment F-W so indicate. Indeed, F-W do not question the key finding that the residuals (which measure changes in the returns on securities) over the adjustment period are initially the same for companies whose financial reporting were and were not affected by the Act.

12. "The residuals ... indicate that both disclosure and nondisclosure firms performed better in the post-*SEC* than in the pre-*SEC* periods...." First, the reduction in variance did not occur until mid-1933 or mid-1936, depending on how one sees Figures 1 and 2. Second, R. R. Officer concludes that the decrease in share price variability on the New York Stock Exchange was not due to the creation of the *SEC* but to fluctuations in business conditions: "The variability of the market factor in the 1920's and before is similar to postwar variability, and the *SEC* was not formed until 1933" (p. 436). Third, while F-W have the quote given in fn. 9 right, they apparently overlooked the fact that the reference (to months) refers to Figures 1 and 2 rather than to Table 3 which presents two-year averages. Fourth, the relevant test, as indicated in my article, is the difference in the residual variability, etc., of the disclosure and nondisclosure corporations, not in the change in variability of all corporations over time.

13. "Thus Benston's conclusion [based on the standard deviations of the residuals] may be questioned from his own results," and the previous paragraph. I believe a rereading of my paper will show the contrary. The insignificantly greater positive algebraic residuals in the first period after the transition period indicate greater revaluations for the disclosure than for the nondisclosure corporations, if anything. The lower post-*SEC* mean standard deviations of residuals for both groups are not relevant to the hypothesis (see paragraph 12).

14. "It is only in the 1920's that a higher ratio is observed, and the size of that ratio (354 percent) might suggest an excessive use of the securities markets in the 1920's

or a mistake in arithmetic." The ratio was taken correctly from the source cited in the author (1967, p. 68, cited in F-W), where an explanation for the size of the ratio is given. But how does one define "excessive?" Further, are F-W satisfied with corporations' use of capital markets to finance capital expenditures not having returned to pre-*SEC* levels until after 1948?

15. "... ranking of industries by the percentage of private placements to total debt issues ... appears impressive mainly because ... [three of the eight] industries have relatively unique methods of debt financing" (fn. 11). Not so. The rankings of the remaining five industries are in the order predicted with one exception. Nor is the comment that "... the importance of private placements has markedly decreased since [1966]" relevant. It would be surprising had investors and corporations not been able to adjust for the *SEC*'s restrictions on the transmission of information by this date.

16. "... Benston considers a market fair in which corporate insiders make large profits at the expense of other investors so long as this is accomplished quickly." I never said this, though given profitable insider trading (which regulation apparently has not eliminated; see Jeffrey Jaffe), it would be better if whatever information the insiders had was impounded in the market price of shares as quickly as possible. The sooner the information is reflected in the prices, the sooner the price at which outsiders buy and sell is "fair." In any event, I know of no reasoning or evidence that supports the assertion that the amount of insider profits or the probability of their occurrence is affected by required disclosure of corporate financial statements.

17. "It is our strong impression, based on reading of ... [cited material] that ... [insider profits] in the pre-*SEC* period were much greater than in the post-*SEC* period." I have reviewed most of the cited materials and have found no more than anecdotes and assertions. Since specific page references were not provided by F-W, I was unable to check my memory. Apparently we both have formed very different impressions based upon roughly the same "evidence." However, to my knowledge there have been no empirical tests performed which have measured the extent of the insider trading profits in the pre- and post-*SEC* period. Until these measurements occur, F-W and I merely hold different subjective opinions.

18. "In a recent paper (Blume and Friend), it was found that in the pre-*SEC* period tested (1928–33) a monthly rebalancing investment strategy ... yielded very much better, though from a statistical viewpoint not necessarily significantly different, results than a buy and hold policy. This was not true in the post-*SEC* period as a whole. One of several explanations for these results would be an increase in market efficiency ... due to securities legislation." First, I do not understand what "very much better, though from a statistical viewpoint not necessarily significantly different, results" means. Second, Blume and Friend (cited in F-W) offer the explanation quoted as half of the first of three possible explanations. (The other half is "... or because of other changes in the institutional environment" (p. 266).) They continue: "A second explanation may be in the unique character of the stock market decline starting in 1929 and, to a lesser extent, in 1937. A third explanation might attribute the impressive differences ... to chance, reflecting the very large dispersion of the underlying distribution of investment returns. The tests reported in footnote 18 are consistent with this last interpretation" (p. 266). No further discussion follows.

I believe a review of F-W's comment will show that I have covered all of the specific criticisms they make of my paper, including those made in footnotes. Should the reader review my paper, I believe he/she will find evidence and additional substantive empirical tests upon which the conclusion of my paper is based.

The Simple Economics of Incentive Contracting: Note

By MICHAEL E. CANES*

In an earlier article in this *Review*, John J. McCall analyzed the effect of certain types of cost incentives on the behavior of firms bidding for government contracts. McCall's major finding was that government sharing in any difference between a firm's bid and actual costs could yield the perverse result that firms whose actual costs are "low" would bid higher than firms whose actual costs are "high," so that the government in selecting the low bidder would choose a high cost firm. Further, the government sharing would result in the high cost firms' submitting cost estimates less than expected costs, so that selection of these firms would result in a tendency toward cost overruns. McCall's findings have important policy implications for they suggest that the government probably has been paying more for its procurements than necessary, that its own policies have been a cause of troublesome cost overruns, and that the type of cost incentive clause analyzed should be excluded from future contracts.

In this note, I shall argue that McCall's findings are the result of a peculiar constraint imposed on the behavior of government contracting officers and of private firms. Further, descriptions of the behavior of contracting officers reported by others seem to contradict McCall's behavioral constraint. Once the constraint is removed, it is shown that the government will choose a "high cost" firm only if it places great weight on a low bid relative to firm willingness to bear deviations of actual costs from bids. Since government contracting officers do not behave as implied by McCall, his conclusions are weakened. Nevertheless, they cannot be entirely dismissed. An alternative policy to that suggested by McCall is proposed herein, and it is shown that the policy will correct the situation while leaving the government the option of sharing in differences between target and actual costs.

I. The McCall Model

Before summarizing McCall's analysis, it is necessary to explain some of the concepts involved. In many procurements and particularly in defense procurement, the government uses a contract type known as "fixed price incentive." In such a contract, a firm provides an estimate of its costs known as a "target cost," and a "target profit" is calculated as a specified proportion of target cost. In addition, any deviation between actual costs and target costs is shared between the government and the firm. Thus, actual costs greater than predicted (cost overruns) reduce firm profits and actual costs less than predicted (cost underruns) increase them, but not by the full amount of the over- or underrun.

The extent of sharing of the difference between target and actual cost is contractually specified. In the extremes, a contractor bears all or none of the deviations of actual from target costs. The former is known as a "firm fixed price" contract, the latter as a "cost-plus fixed fee." This cost sharing arrangement is intended to give contractors incentive to economize while providing that the government bear some of the consequences of deviations between actual and predicted costs. Cost sharing can be beneficial to the government if it can more cheaply bear the consequences of cost overruns than can a contractor.[1]

McCall assumes that firms act to maximize profits by choice of either private sector or government contract opportunities. Profit maximization implies that firms accept government contracts only if their expected profits at least equal those available in the private sector. Under competitive bidding, firm bids for government contracts are set so as to exactly equate expected profits to those available in the private sector.

---

* Assistant professor, Graduate School of Management, University of Rochester.

[1] A contractor can sell off the risk of deviations of actual from predicted costs and hence avoid the consequences. But such sale is itself costly, and presumably the government must compensate a contractor to bear these costs.

McCall first derives his results under assumptions that production costs and private sector receipts are known with certainty, and then proceeds to analyze cases in which these are uncertain. Since no results are significantly changed by relaxing the certainty assumptions whereas simplicity is gained by keeping them, the certainty case is here analyzed.

The notation below follows that of McCall:

C_1 = The actual cost of production, including a return on capital.
C_2 = The cost of the product to the government.
R = Receipts from producing in the private sector.
ρ = Target cost or bid the firm submits.
π_1 = Profits from selling in the private sector.
π_2 = Profits from selling to the government.
α = The target profit rate, a proportion that when multiplied by target costs yields profits; $\alpha > 0$.
$\alpha\rho$ = Target profits.
β = The sharing rate, the fraction of the difference between ρ and C_1 that accrues to the firm; $0 \leq \beta \leq 1$.

From the discussion above, profits derivable from a government contract are given by

$$\pi_2 = \alpha\rho + \beta(\rho - C_1), \qquad \alpha > 0 \qquad 0 \leq \beta \leq 1 \tag{1}$$

and profits in the private sector are[2]

$$\pi_1 = \begin{cases} R - C_1 & \text{when } R > C_1 \\ 0 & \text{when } R < C_1 \end{cases} \tag{2}$$

Under McCall's assumptions, the bid the firm submits on a government contract is calculated by equating π_1 and π_2, and solving for ρ. This yields

$$\rho = \begin{cases} \dfrac{R - (1-\beta)C_1}{\alpha + \beta}, & R > C_1 \\[2ex] \dfrac{\beta C_1}{\alpha + \beta}, & R < C_1 \end{cases} \tag{3}$$

Firms whose private sector receipts exceed production cost are said to be "efficient" or low cost, whereas those whose production costs exceed private sector receipts are "inefficient" or high cost. The important implication of relation (3) is that for an efficient firm, there is a nonpositive relationship between actual costs and bid whereas for an inefficient firm there is a nonnegative relationship.

$$\frac{\partial \rho}{\partial C_1} = \begin{cases} \dfrac{-(1-\beta)}{\alpha + \beta} \leq 0, & R > C_1 \\[2ex] \dfrac{\beta}{\alpha + \beta} \geq 0, & R < C_1 \end{cases} \qquad 0 \leq \beta \leq 1 \tag{4}$$

The crux of the problem is that so long as $0 < \beta < 1$, a firm that expects a cost underrun will bid ***higher*** the *less* his costs of production. In essence, the reason is that with the government sharing in any cost underrun, the less an efficient firm's expected cost, the more it must bid to secure a profit equal to that obtainable in the private sector. This situation can result in inefficient, high cost firms underbidding efficient, low cost ones.

From relation (3), an inefficient firm submits a bid that is below expected costs. Selection of inefficient firms thus results in a tendency towards cost overruns. Also from relation (3), an efficient firm submits a bid below expected cost if $R - C_1 < \alpha C_1$, and above expected cost if $R - C_1 > \alpha C_1$. Thus, selection of efficient firms results in over- or underruns depending upon the sign of the inequality.

Since by assumption the government must pay an efficient firm its private sector alternative and an inefficient firm its costs of production, the relation between government costs and actual costs is

---

[2] McCall assumes that in the long run no firm will endure private sector losses and will always move to another industry in which its profits are zero.

$$C_2 = \begin{cases} R, & C_1 < R \\ C_1, & C_1 > R \end{cases} \tag{5}$$

Awarding of contracts to inefficient firms on the basis of lower bids thus results in higher costs to the government than would be necessary were a different incentive and bidding scheme used.

II. Constraints on the Government and Contractors

McCall's model of contractor behavior is based on premises that α, the profit rate, and β, the sharing rate, are fixed when bids are submitted. This amounts to assuming that government contracting officers are constrained from accepting bids with other than prespecified α and β, and that firms are constrained from offering such bids. To keep the present comment to reasonable length, α will be held fixed by government fiat.[3] But the assumption of a fixed β is inconsistent with government and contractor behavior reported by Frederick Scherer and by John Cross. Both describe negotiations between the government and a single contractor, but their description of government contracting officer behavior provides strong indication of how such officers are likely to view competing bids.

According to Scherer, government contracting officers bargain both for low cost targets *and* high contractor share rates: ". . . generally, the tighter the negotiated cost target is, the higher the sharing proportion desired by the government" (p. 220).

In Cross' view, contractors charge for increases in share rates by raising target costs, and such raising lessens the probability that a cost overrun will occur. According to Cross,

> . . . unexpected contractor cost overruns may appear to reflect upon [procurement officer] performance and to compromise his career . . . [therefore] the government may be expected to *behave* as though it, too, had a strong aversion to risk [i.e., to high government share rates] and, hence, a preference for relatively expensive insurance policies [i.e., for paying a contractor to accept a high share rate]. [p. 211]

Further, "the buyer has always shown some preference for firm fixed price contracts, and, although contract type is usually specified by the government before any bids are taken, a contractor who offers a more stringent type of contract has a considerable advantage over his fellows" (p. 215).

Following Scherer and Cross, it is assumed that government procurement officers prefer high contractor share rates to lower. And following McCall, it is assumed that the government prefers lower cost targets to greater. The implications of making both of these assumptions will now be explored.

III. Implications of Government Preferences for High Sharing Rates and Low Target Costs

Recalling expression (3), for an inefficient firm, a higher share rate dictates a higher bid; that is,

$$\frac{\partial \rho}{\partial \beta} = \frac{\alpha C_1}{(\alpha + \beta)^2} > 0 \tag{6}$$

Thus, an inefficient firm competing for a contract faces a tradeoff between ρ and β. Given the assumptions of the model, such a firm will accept an increased share rate only if it simultaneously increases its target cost. I shall return to this shortly.

For an efficient firm,

$$\frac{\partial \rho}{\partial \beta} = \frac{\alpha C_1 - (R - C_1)}{(\alpha + \beta)^2} \tag{7}$$

Expression (7) is negative if $R - C_1 > \alpha C_1$. In this case, an increase in a firm's share rate allows it to *reduce* its target cost. Thus, an efficient firm with $R - C_1 > \alpha C_1$ can compete for a government contract by simultaneously appealing to government preferences in two dimensions, target cost and share rate. This situation is illustrated by curve I on Figure 1. If $1/\rho$ and β are goods to

---

[3] If firms are allowed to vary α and if they believe it is target profit ($\alpha\rho$) and not the profit rate with which the government is concerned, then for a given target profit, target costs can be set arbitrarily low with profit rate set so as to earn the firm its opportunity cost of capital. Under such conditions, *all* firms will submit bids that are arbitrarily close to zero.

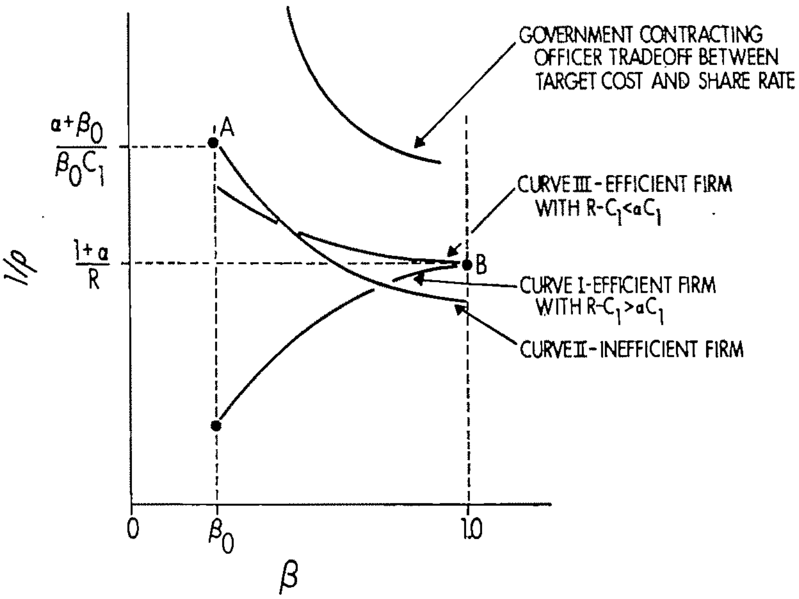

FIGURE 1. BIDS AND SHARE RATES ON GOVERNMENT PROCUREMENT CONTRACTS

government contracting officers, then an efficient firm will move to the northeast along that curve.[4]

Were costs certain and were the share rate not constrained between zero and one, such a firm would reduce target cost to an amount incrementally above its actual cost, with a share rate sufficiently great to cover opportunity costs of accepting the defense contract. However, in actual government contracting the share rate is constrained to be no greater than one. Thus, such a firm bids

$$\rho = \frac{R}{1+\alpha} \qquad (\beta = 1) \tag{8}$$

This is shown as point B in Figure 1.

What does an inefficient firm bid? Apparently, if the firm could obtain a zero share rate (a cost-plus arrangement), it would estimate a zero cost of production. But this is nonsense, for the government would not accept such a bid. Assume that there is some minimum share rate β_0 below which no bids will be accepted. Then an inefficient firm which minimizes its target cost subject to the minimum share rate bids

$$\rho = \frac{\beta_0 C_1}{\alpha + \beta_0} \tag{9}$$

This bid corresponds to point A on Figure 1.

An inefficient firm might choose to increase the share rate it would accept while increasing its bid (i.e., move to the right along curve II). But such a firm's bidding advantage lies in a low target cost-low share rate arrangement, for higher share rates force it to reveal its actual costs. If the inefficient firm has very high costs, then it will be unable to compete with an efficient firm regardless of the share rate it chooses. But over a range of costs, it is possible that an inefficient firm with a low share could submit a lower bid than an efficient firm offering a share rate of one. Such a situation is shown in Figure 1, with point A above point B. In that case, a government contracting officer choosing between an inefficient firm and an efficient firm chooses between a lower target cost, minimum share rate bid and a higher target cost, share-rate-equal-to-one bid. Only if the contracting officer's preference for lower bids outweighs that for higher share rates will the contract go to the inefficient firm.

---

[4] The argument is more complicated if returns from the government project are uncertain, if investors are risk averse in the sense of desiring less variance in a probability distribution over the future returns of their assets, and if there is positive covariance between returns on the government project and those of a market-wide portfolio of assets. In that case, a profit-maximizing efficient firm with $R-C_1>\alpha C_1$ would increase ρ with an increase in β if the market premium for the increased covariance absorbed by the firm were greater than the dollar reduction in government share of a cost underrun. This, however, is not the case analyzed by McCall, and hence will not be followed up here. David Baron has analyzed a somewhat similar problem under the assumption that firms themselves are risk averse.

What of the efficient firm subject to $R-C_1<\alpha C_1$? This inequality is equivalent to expression (7) being positive, so that the firm increases its bid with an increased share rate. If the firm chooses the minimum share rate β_0, then according to expression (7), such a firm bids

$$\rho = \frac{\beta_0 C_1 + (R - C_1)}{\alpha + \beta_0} \tag{10}$$

By expression (9) this bid exceeds that of an inefficient firm by the amount $(R-C_1)/(\alpha+\beta_0)$. But comparing expressions (6) and (7), an efficient firm raises its bid by less with an increase in share rate than does an inefficient firm. Since such a firm is at a competitive disadvantage relative to an inefficient firm at $\beta=\beta_0$, it is to its advantage to compete via higher share rates. Were it to select a share rate of one, then it would bid exactly as does an efficient firm with $R-C_1<\alpha C_1$ (point B on curve III). But it cannot be here determined exactly what such an efficient firm would bid. Presumably that would depend on the firm's beliefs regarding the government's tradeoff between target cost and share rate. The conclusion again is that a government officer confronted with bids from both efficient and inefficient firms will have to choose between a lower target cost with lower share rate, and a higher target cost with higher share rate.

IV. Actual Firm Behavior

Under the assumptions of the model presented, some efficient firms will compete for government contracts by simultaneously increasing the share rate they will accept and reducing their target cost. But Scherer describes contractor behavior as follows: "... the tighter the negotiated cost target is, the lower the sharing proportion a profit maximizing contractor wants" (p. 220). And Cross, p. 210, asserts that contractors charge for higher share rates by raising target costs. This information suggests that only inefficient contractors and efficient contractors with $R-C_1<\alpha C_1$ compete for government procurement contracts.[5] By earlier arguments, these are exactly the class of firms who submit bids below their expected costs. Thus, a systematic tendency towards cost overruns can be expected for the type of contracts here analyzed.

V. A Policy Alternative

From the above discussion, efficient firms can be distinguished from inefficient firms by varying the share rate and choosing the contractor who raises his bid by least. But such a strategy, once discovered by contractors, would surely influence their bidding behavior so as to destroy its advantage.

McCall suggests that the government might set the share rate β equal to one for all procurement contracts. This would induce contractors to reveal their actual costs of production and so would allow the government to select the low cost bidder. But the government would then lose the option of sharing in cost overruns, and under conditions in which the government can more cheaply bear the consequences of an overrun than private contractors, this loss would raise costs to the government.

An alternative would be to set the profit rate α at zero for all cost incentive contracts. Under these conditions, expression (3) collapses to

$$\rho = \begin{cases} \dfrac{\beta C_1 + R - C_1}{\beta}, & R > C_1 \\ C_1, & R < C_1 \end{cases} \tag{3'}$$

According to this expression, inefficient contractors bid exactly their expected costs, independent of the value of β. Further, efficient contractors would be placed in a situation in which they could simultaneously reduce their bid and increase their share rate. Under the assumption that they would set $\beta=1$, (3′) thus collapses to

---

[5] But as noted earlier in fn. 4, under an alternative set of assumptions this behavior does not preclude competition for contracts by efficient contractors with $R-C_1>\alpha C_1$.

$$\rho = \begin{cases} R, & R > C_1 \\ C_1, & R < C_1 \end{cases} \tag{3''}$$

Under these conditions, the government could select the low cost bidder while retaining the option to share deviations between actual and predicted costs. Further, in a situation in which an inefficient firm was the low cost bidder,[6] its selection would result on average in neither a cost over- nor underrun. If an efficient firm were selected, there would result on average an underrun in the sense that actual costs would be below the firm's bid, but neither an overrun nor an underrun in the sense that actual costs to the government would equal its predicted costs. Thus, setting the profit rate equal to zero on fixed price incentive contracts would reduce both expected costs and expected cost overruns on government procurements.

VI. Conclusion

By relaxing an assumption made in an earlier paper by McCall, it has been shown that profit-maximizing behavior by contractors will lead to a different form of competition for government procurement contracts than he suggests. In particular, contractors should be expected to compete both in the bid they submit and the share rate they accept, and inefficient firms will be awarded contracts only if government contracting officers place great weight on a low bid relative to a high share rate. Nevertheless, McCall's principal conclusion that fixed price incentive contracts with share rates between zero and one could result in the government awarding procurement contracts to inefficient firms cannot be dismissed. A suggested policy alternative is to base firm profits only on the deviation of actual from bid costs, i.e., set the target profit rate at zero while allowing firms to choose share rates subject to some minimum rate greater than zero. Such a policy would allow the government to minimize its cost of procurement while inducing firms to reveal their true opportunity costs of producing for the government.

The Principal Cause of Salary Differentials: Research Output or Experience?: Comment

By WILLIAM HAMOVITCH AND RICHARD D. MORGENSTERN*

David Katz's article in this *Review*, "Faculty Salaries, Promotions, and Productivity at a Large University," which estimates the importance of teaching, research, administrative, and other activities in determining faculty salaries, leaves the reader with an impression that is not supported by the data: namely, that research performance is the single most important determinant of academic salaries. We believe that a careful examination of Katz's own data, as well as the results of other studies, indicate that an equally or more important determinant of faculty salaries is years of experience.

The problem of interpreting Katz's results is really an exercise in stock-flow analysis. Because articles and books published are measured as a lifetime stock, it is necessary to deflate these totals by the years over which they were accumulated in order to get a true picture of the relative importance of these so-called productivity measures compared to experience (years since highest degree) in determining faculty salaries. If this adjustment is not made, the large coefficients on the variables representing publications make it appear that these variables account for the largest part of the differences in salaries among individuals. However, one must recognize that the average individual publishes relatively few books and articles over his career. When all four of Katz's productivity measures (books, articles, excellent articles, and dissertations supervised) are transformed (from his linear equation) and added together, the result is clear: whereas the average year of professional experience is worth $189, the average year's research output is worth $151, or roughly three-quarters as much. If we restrict the productivity variable to the three which include actual publications of books, articles, and excellent articles, the average year's research output is worth $61, or roughly one-third as much as the average year of professional experience. Alternatively, using the partial non-linear estimates presented by Katz for books and articles (which show diminishing returns), the comparable average year's research output is worth $270 when dissertations supervised are included, and $161 when only actual publications are used.[1]

Of the numerous studies that have been conducted on the determinants of faculty salaries, few have actually used such detailed productivity measures as publications. Presumably for lack of data, most have applied a more aggregated analysis and examined only such factors as field of specialty, years of experience, highest degree, and sex. However, several recent studies of individual institutions and of national faculty populations have included measures of research and publications in their analyses of faculty salaries (see John J. Siegfried and Kenneth J. White, Alan E. Bayer and Helen S. Astin, Astin and Bayer, and the authors). When we transformed the findings of these studies in a manner comparable to our transformation of the Katz data, the results showed that by a considerable margin, years of experience had a larger impact in determining salaries on a per year basis

---

* Professor of economics and assistant professor of economics, respectively, Queens College, City University of New York.

[1] The precise calculation for the impact of research, publications, and graduate teaching is the annualized sum of the regression coefficients on the respective variables; that is, each variable coefficient is multiplied by the average value for that variable and then divided by the number of years over which it accrued. The resulting values are then summed. The number of years is 13.13 for all variables except dissertations which is 6.

than did annual research output. In our own study of Queens College, which has a policy of automatic salary increments within each rank, we found that a year's teaching experience was worth almost nine times as much as an average year's research output.

The purpose of this note is to point out the importance of years of experience in determining faculty salaries. Although Katz's study shows research output to be an important factor in salary determination, actual number of years experience appears to be of, at least, approximately equal importance. And, in other studies, experience is found to be by far the most important determinant of faculty salaries.

The obvious question raised by this interpretation is the reason for the high rewards to experience. While the differential rewards for years of service may be due in part to the quality of the overall contribution to the institution, we suspect that a larger part of the salary differential is unrelated to rational market behavior; instead, it probably represents the common practice of rewarding seniority, independent of productivity.

The Principal Cause of Salary Differentials: Research Output or Experience?: Reply

By DAVID A. KATZ*

William Hamovitch and Richard Morgenstern (H-M) are certainly correct in saying that experience is at least as important as research output in the determination of salaries. However, a professor will probably never gain any considerable experience at a prestigious university unless he publishes; instead, he will be fired. This is demonstrated by the fact that only 6.4 percent of the associate professors at the time of promotion to that rank had published nothing as compared to 22.4 percent for assistant professors who had not yet been promoted. Only 1.6 percent of the full professors at the time of promotion had published nothing.

The existence of diminishing returns to publishing lends support to H-M's conclusion that experience is possibly the most heavily weighted factor in the reward process. To ignore, though, the very large contribution which publication makes in the salary and promotion process would significantly reduce the predictability of the model. Given the diminishing returns to publishing and the high relative rewards to experience, why do professors continue to publish after gaining tenure? Nonpecuniary rewards—prestige and self-satisfaction—would then explain their behavior. H-M suggest that "a larger part of the salary differential is unrelated to rational market behavior." Actually the opposite may be true. If professors are willing to do research at low pay because of the nonmonetary rewards, why pay them any more than is necessary?

Segmentation of the Labor Market: Comment

By JOHN M. BARRON*

It has been suggested by Charles Holt in his paper "Improving the Labor Market Trade-Off Between Inflation and Unemployment" (1969) and, in more detail, in the volume edited by Edmund Phelps, that a segmentation of the labor market leads to an increase in the unemployment rate. One purpose of this comment is to clarify the effect of a division of the market for labor services using a model similar to that proposed by Holt. In examining the common notion that combining formerly separated labor markets improves the aggregate performance of an economy, it becomes clear that whether improvement results depends on certain assumptions to be discussed. This result is important in light of the general unqualified feeling that centralized (federalized) manpower programs would reduce structural unemployment (see Holt et al.).

Consider an economy consisting of m firms. Let j_t denote the number of employment positions at the m firms in period t. Define

l = number of people in the labor force (constant)
e_t = number employed in period t
u_t = number unemployed in period t
v_t = number of vacancies in period t

The following relations hold:

$$l = e_t + u_t \quad \text{and} \quad v_t = j_t - e_t$$

To permit a simple presentation, it is assumed that in any given period there is not more than one vacancy per firm.

The model considers a random search procedure by the unemployed workers. In one period, an unemployed worker contacts k firms. A period is defined such that k is sufficiently small ($k<1$) so that the probability of more than one searcher contacting the same firm in a given period approaches zero (a similar assumption is made by Reuben Gronau). For the individual, the average time (number of periods) taken to visit one firm is $1/k$. If there is only one vacancy existing in the economy, the expected number of periods, the "mean search time," before this vacancy is located by a particular searcher is $(1/(1/m))(1/k)$ or m/k.[1] To simplify notation, $\mathrm{T}=(m/k)$ is substituted in the following discussion. Given v_t vacancies, the probability that an individual engaged in a random search process will locate a vacancy in one period is v_t/T.

Let P_e denote the average probability that on finding a vacancy, employment is attained. Thus the probability of employment in period t is $(P_e \cdot v_t)/\mathrm{T}$ for the individual. Aggregating, the total flow of unemployed people into employment, i.e., the flow of hires per period, F, is

$$F = \frac{P_e v_t u_t}{\mathrm{T}} \tag{1}$$

Note that u_t and v_t are stock concepts, F is a flow concept.

Let f_t denote the flow of new entrants into the labor force in the t-th period. It is assumed that new entrants enter the stock of unemployed and proceed to search for vacancies. Let q_t and s_t denote, respectively, the number of people who enter the ranks of the unemployed through quits or layoffs. Then,

$$u_{t+1} - u_t = q_t + s_t + f_t - F \tag{2}$$

Let r_t denote the number of people that retire from employment in period t. Denote the number of new positions created in the t-th period by x_t. Then,

$$v_{t+1} - v_t = q_t + x_t + r_t - F \tag{3}$$

---

* Graduate student, Brown University.

[1] This expected time to locate the vacancy is a random variable having a geometric distribution with parameter (k/m).

In a steady state, $F=q_t+s_t+f_t=q_t+x_t+r_t$. The resulting u_t and v_t may be denoted the equilibrium number of unemployed workers and vacancies. Assuming an equal number entering and leaving the labor force ($f_t=r_t$), maintenance of a steady state requires that the number laid off by certain firms equal the number of new workers required by other firms each period. In the following analysis, it is assumed that the aggregate labor market flows other than hires are constant over time.

Consider an exogenous change, such as an increase in k, signifying an efficiency improvement in the search procedure. The variable T is reduced and F, the flow of hires, increases. Starting from a position of equilibrium, the effect is a negative change in the stock of unemployed workers and vacancies until F has decreased back to its original level. Naturally, this outcome implicitly assumes other things constant. One might, for example, expect P_e to change which may partially offset the above effect. Nevertheless, the implication remains that a reduction in the equilibrium number of unemployed workers results from a more efficient search process.

Now, consider a splitting of the economy into N identical sectors. Holt states that u_t and v_t "would each tend to be increased by a factor of $\sqrt{N}$ as the result of compartmentalization compared to a unified market" (1970, p. 237). A version of his proof follows.

(4) $u_t^i=u_t^d/N=$ number unemployed in the ith sector

(5) $v_t^i=v_t^d/N=$ number of vacancies in the ith sector

where d designates aggregate unemployment and vacancies for a divided economy. Aggregate unemployment u_t^d may differ, as the result of segmentation, from u_t. Employing equation (1),

$$F^i = \frac{P_e u_t^i v_t^i}{\mathrm{T}} \tag{6}$$

where F^i is the flow of hires per period in the ith sector. Defining

$$\sum_{i=1}^{N} F^i = F^d, \quad \sum_{i=1}^{N} u_t^i = u_t^d \tag{7}$$

and
$$\sum_{i=1}^{N} v_t^i = v_t^d$$

and summing equation (6),

$$F^d\mathrm{T} = P_e \sum_{i=1}^{N} u_t^i v_t^i \tag{8}$$

where d again refers to the aggregate value after division of the economy. In the undivided economy, from equation (1),

$$F\mathrm{T} = P_e v_t u_t \tag{9}$$

To maintain the same rate of flow of hires in the divided economy as in the one not divided requires that $u_t v_t = \sum_{i=1}^{N} u_t^i v_t^i$. But, given the above definitions for u_t^i and v_t^i

$$\sum_{i=1}^{N} u_t^i v_t^i = \frac{u_t^d v_t^d}{N} \tag{10}$$

Therefore, to maintain the same aggregate flow F, aggregate unemployment and vacancies must increase due to segmentation. Or, starting at the original aggregate level of unemployment, F falls leading to rising unemployment and vacancies, to the point where u_t and v_t may increase by the factor $\sqrt{N}$.

This conclusion by Holt rests on the assumption that P_e and T are unchanged by dividing the economy. However, his idea of compartmentalization is the isolation of regions. Given a random search procedure, this reduction in the number of firms in each "sub"economy by a divisor of N, so that the number is m/N, directly affects the probability of locating a vacancy. Specifically,

$$\mathrm{T}^i = (m/N)/k \tag{11}$$

This alteration in T is necessary due to the reduced number of firms to search in the ith sector. Returning to equation (6), now

$$F^i = \frac{P_e u_t^i v_t^i}{\mathrm{T}^i} \tag{12}$$

Multiplying by N/N

$$F^i = \frac{P_e u_t^i v_t^d}{\mathrm{T}} \tag{13}$$

or
$$F^i\mathrm{T} = P_e u_t^i v_t^d$$

Following the same procedure as before, equation (1) states that

$$FT = P_e u_t v_t \tag{14}$$

For the economy after segmentation, using equations (7) and (13), we have

$$\sum_{i=1}^{N} \overset{i}{F}T = \overset{d}{F}T = \sum_{i=1}^{N} P_e \overset{i}{u}_t \overset{d}{v}_t \tag{15}$$

But

$$\sum_{i=1}^{N} P_e \overset{i}{u}_t \overset{d}{v}_t = P_e \overset{d}{u}_t \overset{d}{v}_t \tag{16}$$

Note that equation (16) implies no change in the aggregate flow of hires due to compartmentalization. Thus by the above, it is proven that a division of the economy, since the model dictates an adjustment of T for the individual sectors, does not lead to a change in the aggregate level of unemployment or vacancies.

The above appears to contradict the intuition that barriers increase unemployment and vacancies. That intuition may be correct, but it requires a different formulation than given above.

For example, if the market is unknowingly subdivided, such as by discriminatory practices, then T is not reduced, since the individual will approach randomly all apparent employers. What has occurred is that, for those discriminated against, there is de facto a reduction in vacancies, leading to increased unemployment. Or, one might interpret the effect as a reduction in P_e, the average probability of an offer and acceptance of a job, a vacancy having been located. Again, unemployment is increased for this element of the economy—the discriminated worker.

A second implication of the analysis comes by dropping the equal division of unemployed workers and vacancies within equal subdivisions of firms. In the examples that follow, the distribution of vacancies and unemployment in the subeconomies becomes crucial in analyzing the implications. Assume the number of firms in each sector is $1/N$ times the number in the economy; T is reduced by the factor $1/N$ also, as has been seen. But assume the vacancies and unemployed have been separated unequally into the N regions. From equations (11) and (12)

$$\overset{i}{F}T = NP_e \overset{i}{u}_t \overset{i}{v}_t \tag{17}$$

Then

$$\overset{d}{F}T = NP_e \sum_{i=1}^{N} \overset{i}{u}_t \overset{i}{v}_t \tag{18}$$

$$= NP_e(\overset{1}{u}_t \overset{1}{v}_t + \overset{2}{u}_t \overset{2}{v}_t + \dots \overset{N}{u}_t \overset{N}{v}_t)$$

Designate a "pure mismatch" effect as the division of the economy such that in a sector with unemployment above the mean u_t/N, there are vacancies below the mean v_t/N. In this case, it is clear that aggregate unemployment will be higher in the divided economy than if the economy were not split. With a given aggregate number of unemployed and vacancies, the aggregate flow of hires in an economy so divided, as determined by (18), will be less than that of an undivided economy as determined by (9). Designate a "pure match" effect as the division of the market such that in a sector with unemployment greater than or equal to the mean, there are vacancies greater than or equal to the mean. Then it is clear that aggregate unemployment will be below or equal to the level of unemployment before subdivision. One case of equality, discussed previously, occurs when there is an equal division of u_t and v_t among the N sectors. The pure match effect is due to economies of scale in the placement flow. Holt recognized the existence of economies of scale, but failed to accurately state conditions under which they could occur.

A third example is often the one behind intuition concerning the segmentation of markets. Assume that there are Q different nonsubstitutable types of labor. In the extreme case, the market would be divided into Q isolated regions; within each would be the entire unemployed in one category of workers while the vacancies within the region would be those of other categories. In such an extreme, the flow of hires would be zero in the aggregate. This may be likened to an extreme pure mismatch effect, in which in each region the unemployed are mismatched with zero vacancies.

Segmentation of the Labor Market: Rejoinder

By CHARLES C. HOLT*

The comment by John Barron constitutes a very interesting extension of earlier work rather than a correction of it. He introduces the additional dimension of searching firms to find vacancies. The earlier work had concentrated on the searching of vacancies to find job offers. Clearly both are relevant and, not surprisingly, he finds that when different assumptions are made, different conclusions follow.

He introduces the concept of mean (firm) search time T to find a particular firm with a vacancy in a given set of firms. Assuming random search, this time depends on the number of firms in the set. Thus, he finds that when a labor market is divided into N equal compartments, mean search time in each compartment is reduced by a factor of $(1/N)$.

The earlier work to which he refers implicitly assumed that the vacancies in a compartment could be located fairly readily. The hiring firms could be easily located but time consuming search was required to determine the particular vacancies which would produce job placements for particular workers. Thus, the relevant search time measure is the mean (vacancy) search time to locate a placement from the set of vacancies in the compartment. This search time depends only on the number of vacancies and is not affected by the number of firms over which the vacancies are scattered. Both concepts of search time are relevant and a comprehensive theory would distinguish between time to search firms for vacancies and time to search vacancies for placements.

Barron finds the aggregated flow relation under his assumption to be

$$F = \sum_{i=1}^{N} \frac{(v/N)(u/N)}{\left(\frac{m}{k}\right) \mathrm{x} \left(\frac{1}{N}\right)}$$

in which the number of compartments N cancels out and has no effect. This cancellation does not occur in the other case in which the mean time to search a vacancy is unaffected by the number of firms in the labor market compartment.

One interpretation of Barron's result is that the search of firms depends only on the probability that a firm will have a vacancy $(v/N)/(m/N)$. Clearly this probability is unaffected by the degree of compartmentalization as reflected in N.

Barron's comment opens up an interesting line of theoretical and empirical work. One essential refinement is to deal with scale effects.

---

The Elasticity of Scale and the Shape of Average Costs

By GIORA HANOCH*

The theory of production deals with two different concepts of returns to scale. The first, which is most widely used for *defining* returns to scale,[1] is the relative increase in output as all input quantities are increased proportionally along a ray through the origin. The second, which is the more relevant concept for micro-economic analysis, is the increase in output relative to costs for variations along the expansion path where input prices are constant and costs are minimized at every output.[2]

As it turns out, these two concepts yield equal measures for the Elasticity of Scale[3] ϵ at every minimum-cost point in the input space.

However, *the change in ϵ with output* is generally different for the two concepts,[4] since expansion paths do not coincide with rays, unless the production function is *homothetic*.[5] But it is the change of ϵ along the expansion path—and not along the ray—which determines the shape of the average cost curve (AC), and which is therefore relevant for the analysis of firms and industry behavior under competition.[6]

These relations are stated and analyzed below. It is shown that assumptions made in the literature[7] which are related to the behavior of ϵ along rays, or to the slope of the technically optimal surface (where returns to scale are locally constant), are irrelevant—being neither necessary nor sufficient for implying classical U-shaped average cost curves.

The following definitions and results are used here:

(a) A production function $y=f(x_1, \ldots . x_n)=f(x)$ is denoted ***regular*** at x, if it satisfies the following conditions at a (strictly positive) point x:

> $f(x)$ is positive, finite, continuously twice differentiable, strictly monotone and strongly[8] quasi concave at x; i.e., $f(x)>0$, $f_i(x)=\partial f/\partial x_i>0$, and $(-1)^i|B_i|>0$, for $i=1, \ldots, n$ where:
>
> $$B_i=\begin{bmatrix} 0 & f_1 \cdots f_i \\ f_1 & f_{11} \cdots f_{1i} \\ \vdots & \vdots \quad\quad \vdots \\ f_i & f_{1i} \cdots f_{ii} \end{bmatrix}=\begin{bmatrix} 0 & f_x^{i\prime} \\ f_x^i & H_i \end{bmatrix}$$
>
> H_i is the Hessian matrix of order i, and B_i is H_i bordered by the marginal products $f_X^{i\prime}=(f_1, \ldots, f_i)$.

(b) $f(x)$ is denoted *concave regular* at x, if it is regular and strongly concave. That is: $H_i(x)$ is negative definite, satisfying:

---

* Hebrew University and Harvard University. Financial support was received from the National Science Foundation (Grant No. G.S. 39865X). I thank Gary Chamberlin, Zvi Griliches, Ed Leamer, and a referee for comments.

[1] See, e.g., Sune Carlson, Leif Johansen, Ragnar Frisch, F. W. McElroy (1964).

[2] The distinction between these concepts dates back to Francis Edgeworth. But many subsequent writers failed to make this distinction, or to realize its full implications (see fnn. 4, 17, and 20 below).

[3] The Scale Elasticity (see Johansen, p. 64) is known under various names: e.g., "elasticity of production" (W. E. Johnson, p. 507); "passus coefficient" (Frisch, p. 65); "function coefficient" (Carlson, p. 17). Its reciprocal is the elasticity of costs, or the "substitumal cost flexibility" (Frisch, p. 167).

[4] Qualitatively, this difference was pointed out by John Rowe, in his comments on Albert Levenson and Babette Solon, and McElroy (1967). Rowe showed that at a point of maximum marginal returns to scale along the ray, the two variations in ϵ may differ (for two factors).

[5] The term was introduced by Ronald Shephard, to define a monotone transform of a positive homogeneous function. On different definitions of homotheticity and proofs of their equivalence, see Lawrence Lau, and the author.

[6] See Lowell Bassett and Thomas Borcherding, C. E. Ferguson and Thomas Saving, S. Charles Maurice, and Dale Truett and Blaine Roberts, among others, on relations between cost curves, factor prices, and firm and industry size under competition.

[7] E.g., Frisch, p. 171; Truett and Roberts, etc.

[8] "Strongly" means "strictly differentiably." See Peter Newman.

$(-1)^i|H_i|>0$, for $i=1,\ldots,n$. It may be shown, however, that $(-1)^n|H_n|>0$ is sufficient for a regular $f(x)$ to be concave regular at x.[9]

(c) Necessary conditions for minimizing (variable) costs $c=\Sigma p_i x_i$ at $x \gg 0$ under given $p \gg 0$ are:

$$(1) \qquad \lambda f_i(x) = p_i; \qquad i = 1, \ldots, n$$

These conditions are also sufficient if $f(x)$ is regular. The points x satisfying (1) for given p constitute an *Expansion Path.*

(d) By Shephard's Duality Theorem,[10] the (minimum) *cost function* $c(y, p)$, dual to a regular $f(x)$, satisfies the following conditions:

> $c(y, p)$ is finite, positive, continuously twice differentiable, and strictly monotone in (y, p), and linear homogeneous and concave in p. Along the expansion path, $c(y, p)$ satisfies:

$$(2) \qquad \frac{\partial c}{\partial p_i} = x_i; \quad \frac{\partial c}{\partial y} = \lambda; \qquad (i = 1, \ldots, n)$$

Hence $\lambda=\lambda(y, p)$ is marginal cost.

(e) The Average Cost function $AC(y, p)=c/y$ is denoted U-*shaped* (for given p), if it has a unique minimum with respect to y. That is, if $\partial AC/\partial y=0$ for some $y>0$, and $\partial AC/\partial y=0$ implies $\partial^2 AC/\partial y^2>0$. Equivalently, AC is U-shaped if $AC=\lambda$ for some y, and $AC=\lambda$ implies $\partial\lambda/\partial y>0$.

(f) A production function which yields U-shaped AC curves for all $p \gg 0$[11] is denoted *classical.*

I. The Elasticity of Scale and Its Variation with Output

For $f(x)$ regular, the Elasticity of Scale $\epsilon(x)$ is defined as follows:[12]

$$(3) \qquad \epsilon(x) = \left.\frac{\partial \log f(kx)}{\partial \log k}\right|_{k=1} = \frac{\Sigma f_i x_i}{y}$$

Equation (3) is sometimes denoted the "generalized Euler equation," since if $f(x)$ is homogeneous of degree ϵ, satisfying $f(kx)\equiv k^\epsilon f(x)$, then $\epsilon(x)\equiv\epsilon$.

The cost (not necessarily minimal) of producing $f(kx)$ at fixed x and p, is $\bar{c}=k\Sigma p_i x_i$, with $\partial \log \bar{c}/\partial \log k=1$. Therefore:

$$(4) \qquad \epsilon(x) = \left.\frac{\partial \log f(kx)}{\partial \log \bar{c}}\right|_{k=1}$$

providing another interpretation of $\epsilon(x)$ as the elasticity of output with respect to costs along the ray kx, for any arbitrary prices p.

To derive the alternative concept of the elasticity of scale, related to the cost function, substitute equations (1) and (2) into (3):

$$(5) \quad \epsilon(x) = \frac{\Sigma p_i x_i}{\lambda y} = \frac{c}{\lambda y} = \frac{AC}{\lambda}$$
$$= 1 \Big/ \frac{\partial \log c(y, p)}{\partial \log y} = \left.\frac{\partial \log y}{\partial \log c}\right|_p$$

where the last derivative is taken along the expansion path through x. Equation (5) thus establishes the equality of $\epsilon(x)$ for the two concepts.

The change in $\epsilon(x)$ with y along the ray kx (for x constant, at $k=1$) is derived as follows:

$$(6) \quad \left.\frac{\partial \epsilon}{\partial y}\right|_x = \left.\frac{\partial \epsilon(kx)}{\partial k} \Big/ \frac{\partial f(kx)}{\partial k}\right|_{k=1}$$
$$= \frac{1}{f(x)}\left[1 - \frac{\Sigma f_i x_i}{f(x)} + \frac{\Sigma\Sigma f_{ij} x_i x_j}{\Sigma f_i x_i}\right]$$
$$= \frac{1}{y}(1-\epsilon) + \frac{1}{y^2\epsilon} x' H_n x$$

This is generally different from the change in $\epsilon(x)$ along the expansion path through x, as derived below.

---

[9] A sketch of the proof is as follows: If $f(x)$ is regular, then at least $(n-1)$ eigenvalues of H_n are negative (by Sturmian Separation Theorem; see C. R. Rao, p. 52). Since $|H_n|$ equals the product of all n eigenvalues, H_n is negative definite, and f concave regular, if $(-1)^n|H_n|>0$.

[10] See Shephard, W. E. Diewert, or Daniel McFadden, p. 44, for proofs and alternative formulations of duality theorems.

[11] This may be restricted to an open convex cone within the positive orthant in the prices-space. Note that properties (e) and (f) are global, rather than local. The term "classical" was used in Truett and Roberts.

[12] See fnn. 2, 4.

First, using the dual cost function, equations (2) and (5) are used to derive $(\partial\epsilon/\partial y)|_p$ in terms of y and p:

$$\text{(7)} \quad \left.\frac{\partial\epsilon}{\partial y}\right|_p = \frac{\partial}{\partial y}\left(\frac{c}{\lambda y}\right) = \frac{1}{y}(1-\epsilon) - \epsilon\left(\frac{1}{\lambda}\frac{\partial\lambda}{\partial y}\right)$$

where $\lambda = \partial c(y, p)/\partial y$.

Next, $(1/\lambda)(\partial\lambda/\partial y)$ is expressed in terms of x, where x is on the expansion path. Differentiating the identity $f(x) = y$ and equation (1) with respect to y (p constant), and solving for $(1/\lambda)(\partial\lambda/\partial y)$ yields:

$$\text{(8)} \quad \frac{1}{\lambda}\frac{\partial\lambda}{\partial y} = [B_n^{-1}]_{00} = \frac{|H_n(x)|}{|B_n(x)|}$$

where $[B_n^{-1}]_{00}$ is the corner element of the inverse matrix of B_n.

Substitution of (8) into (7) finally gives:

$$\text{(9)} \quad \left.\frac{\partial\epsilon}{\partial y}\right|_p = \frac{1}{f(x)}[1-\epsilon(x)] - \epsilon(x)\frac{|H_n(x)|}{|B_n(x)|} = \frac{1}{y}(1-\epsilon) - \epsilon\frac{|H_n|}{|B_n|}$$

Observe that the second right-hand terms in (6) and (9) are different.

II. Technical Optimality and the Scale Elasticity

A point x corresponds to a firm's long-run equilibrium in a competitive industry with similar firms and free entry if and only if the average cost function has a minimum at x, with respect to variations in y along the expansion path through x. A necessary condition for this in view of equation (5) is that $AC = c/y = \lambda$, or that returns to scale are locally constant: $\epsilon(x) = 1$. In addition, $f(x)$ must be concave regular at x, or $\partial\lambda/\partial y > 0$, where $\epsilon = 1$. Points x which satisfy these conditions are denoted "technically optimal." The following proposition relates the change in ϵ with y at a point of local constant returns, to technical optimality at that point.

PROPOSITION 1: *Let $f(x)$ be regular, and* $\epsilon(x) = 1$.

(i) *$f(x)$ is concave regular, and x technically optimal, if and only if* $(\partial\epsilon/\partial y)|_p < 0$.

(ii) *If* $(\partial\epsilon/\partial y)|_p < 0$ *then* $(\partial\epsilon/\partial y)|_x < 0$; *i.e., ϵ is decreasing along the ray at technically optimal points.*

(iii) $(\partial\epsilon/\partial y)_x < 0$ *is not sufficient for* $(\partial\epsilon/\partial y)|_p < 0$; *i.e., ϵ may be decreasing along the ray (and $\epsilon = 1$), but $f(x)$ not concave, such that $AC(y)$ has a maximum and not a minimum at x, with $(\partial\epsilon/\partial y)|_p > 0$ and x not technically optimal (even though average "ray costs" $\bar{c}/y$ are at a minimum).*[13]

PROOF:

(i) By assumptions, $\epsilon = 1$ and $(-1)^n|B_n| > 0$ (f regular). Therefore, $(\partial\epsilon/\partial y)|_p < 0$ if and only if $(-1)^n|H_n| > 0$ by equation (9). But this is equivalent to f concave regular, and x technically optimal.[14]

(ii) By (i), $f(x)$ is concave regular; hence H_n is negative definite, implying $x'H_n x < 0$. But this implies $(\partial\epsilon/\partial y)|_x < 0$ by equation (6).

(iii) The proof of this part is by example. Consider the function:

$$f(x_1, x_2) = -\tfrac{1}{2}x_1^2 - 2x_2^2 + 3x_1x_2 - 4x_1 + 6x_2 - 2.5$$

at the point $(x_1, x_2) = (1, 2)$. Then $f(1, 2)$ is regular with: $y = 3$; $f_1 = f_2 = 1$; and $|B_2| = 11 > 0$. At prices $p_1 = p_2 = 1$, minimum costs for $y = 3$ is at $(1, 2)$, with: $c = 3$; $AC = \lambda = 1$; and $\epsilon = 1$. But at the point $(1, 2)$:

$$\left.\frac{\partial\epsilon}{\partial y}\right|_x = -5/9 < 0, \quad \text{whereas} \quad \left.\frac{\partial\epsilon}{\partial y}\right|_p = 5/11 > 0$$

Note that in the last example $f(x)$ is concave at $(1, 2)$ along the following directions: The ray (with a slope $(\partial x_2/\partial x_1)|_{x_2=2x_1} = 2$); the tangent to the isoquant (with a slope $(\partial x_2/\partial x_1)|_{y=3} = -1$); constant $x_1 = 1$ and constant $x_2 = 2$ (i.e., $f_{11} < 0$ and $f_{22} < 0$). But it is *convex* along the expansion path (which has a positive slope: $(\partial x_2/\partial x_1)|_p=4/7)$, and along the line of constant returns (which is also positively sloped: $(\partial x_2/\partial x_1)|_{\epsilon=1}=+1)$.[15]

---

[13] See equation (4) above. Clearly, if $(\partial\epsilon/\partial y)|_x < 0$ and $\epsilon(x) = 1$, then $\bar{c}/y = k\Sigma p_i x_i/y$ has a minimum with respect to k at $k = 1$.

[14] See fn. 10.

In view of (e) and (f) in Section I, Proposition 1 may now be applied globally:

COROLLARY 1: *Let* $f(x)$ *be regular, with* x *satisfying* (1). *Then*:

(i) AC *is U-shaped (for given* p*), if and only if* $\epsilon(x)=1$ *for some* $y=f(x)$, *and* $\epsilon=1$ *implies* $(\partial\epsilon/\partial y)|_p<0$. *That is, iff the scale elasticity decreases through* 1 *along the expansion path.*

(ii) $f(x)$ *is classical, iff (i) holds for all* $p\gg 0$. *That is, iff* ϵ *decreases through* 1 *along any expansion path.*

(iii) $\epsilon=1$ *and* $\{\epsilon=1$ *implies* $(\partial\epsilon/\partial y)|_x<0\}$ *are not sufficient for* AC *to be U-shaped, or for* $f(x)$ *to be classical. That is,* ϵ *decreasing through* 1 *along rays does not in general imply U-shaped* AC *curves.*

III. Firm Profit Maximization and the Scale Elasticity

Long-run equilibrium conditions for a competitive *industry* (with free entry and exit and similar firms) require *zero profits*, and therefore technical optimality ($\epsilon=1$). But an individual *firm* facing a given output price p and $f(x)$ regular, may be at equilibrium with profits positive, and therefore $\epsilon<1$.

The conditions for long-run equilibrium for the firm are thus: $\lambda=p$; $\epsilon\leq 1$, and $f(x)$ concave regular: $(1/\lambda)(\partial\lambda/\partial y)=|H_n|/|B_n|>0$. But substitution of these conditions in equations (7) or (9) does not yield a definite sign for $(\partial\epsilon/\partial y)_p$. That is, the elasticity of scale may be either decreasing or increasing along the expansion path at a point of equilibrium of the firm.

On the other hand, if both $\epsilon\leq 1$ and $(\partial\epsilon/\partial y)|_p<0$, equation (9) implies $|H_n|/|B_n|>0$, and thus $f(x)$ concave regular. This is summarized in the following:

PROPOSITION 2: *Decreasing elasticity of scale along the expansion path* $(\partial\epsilon/\partial y)|_p<0$ *at a point where* $\epsilon(x)\leq 1$ *is sufficient, but not necessary, for the point* x *to be a valid profit-maximizing equilibrium point for a competitive firm.*

IV. Classical Production Functions and the Slope of the Technically Optimal Surface

Frisch and others[16] used the following assumption extensively in their analysis (in addition to regularity of f):

ASSUMPTION F (Frisch's "Regular Ultrapassum Law"): The equation $\epsilon(x)=1$ determines an $(n-1)$ dimensional surface which is downward sloping, so that $\epsilon(x)>1$ below it and $\epsilon(x)<1$ above it, along any upward sloping path of inputs. Formally: $(\partial x_i/\partial x_j)|_{\epsilon=1}<0$ for all $i\neq j$; $i, j=1,\ldots,n$. On any path $x(\theta)$ such that $dx/d\theta>0$, $(d\epsilon/d\theta)|_{\epsilon=1}<0$.

Assumption F was invoked in the belief that it was equivalent to $f(x)$ being classical.[17] However, the following proposition proves that it is irrelevant, since it is neither necessary nor sufficient for U-shaped average cost curves.

PROPOSITION 3: *Let* $f(x)$ *be regular. Assumption F is neither necessary nor sufficient for* $f(x)$ *to be classical, with U-shaped* AC *curves.*

PROOF:

(i) To show that Assumption F is *not necessary*, consider the following function:

---

[15] Although this example is only *locally* regular, a similar behavior may be found for a function which is regular for all x, with both factors normal (positively sloped expansion path), provided the expansion path intersects the line $\epsilon(x)=1$ from an *opposite direction*, compared to the ray. The fact that a function which is concave along the rays (globally) is not necessarily concave (unless it is homothetic) was pointed out by Newman and by James Friedman. But the example in Newman (p. 305; taken from R. T. Rockafellar) is not monotone in x_1, x_2; and the example in Friedman is not regular. Another example, with $\epsilon=1$ a downward sloping curve (but x_2 inferior) is in the proof of Proposition 3 (iii) below.

[16] For example, see Frisch, chs. 8, 10; Truett and Roberts.

[17] See Frisch, pp. 170–71; Truett and Roberts, p. 976. It is not clear whether Frisch considers this assumption equivalent, or merely sufficient, for f being classical. Sometimes, normality of all factors is assumed as well (but see his p. 170). (Frisch's "Law" assumes also that ϵ decreases monotonically, and equals zero at higher outputs, but these are irrelevant for the present discussion.)

$f^*(x_1, x_2) = [x_1^{-1/2}+x_2^{-3/2}]^{-1}$. It is easily verified that f^* is regular and classical. Expansion paths are given by the equation: $x_2=(3p_1/p_2)^{2/5}\cdot x_1^{3/5}$, and the constant returns to scale (*CRS*) line where $\epsilon=1$ is: $x_2=x_1^{1/3}$. We see that ϵ decreases through 1 along any expansion path, hence f^* is classical by Corollary 1 (ii). But f^* does not satisfy Assumption F, since the *CRS* line is positively sloped.

(ii) To show that Assumption F is ***not sufficient***, the following example is given:

$$\bar{f}(x_1, x_2) = 15x_1 + 45x_2 - x_1^2 - 16x_2^2 - 12x_1x_2 - 29$$

$\bar{f}$ is regular at the point (1, 1) and its neighborhood. The *CRS* line is negatively sloped:

$$\left.\frac{\partial x_2}{\partial x_1}\right|_{\epsilon=1} = \frac{-2x_1 - 12x_2}{12x_1 + 32x_2} = -7/22 \text{ at } (1, 1)$$

Also, $\epsilon>1$ below and $\epsilon<1$ above this *CRS* line at points near (1, 1); hence Assumption F is satisfied.[18] But the expansion path through (1, 1), corresponding to prices $p_1=p_2=1$ (which minimize costs for output $y=2$ at $x_1=x_2=1$), is negatively sloped (x_2 inferior), and intersects the *CRS* line ***from above***, with a slope equal to: $(\partial x_2/\partial x_1)|_p = -\frac{1}{2}$. Thus *AC* has a ***maximum*** at $y=2$ ($p_1=p_2=1$), and it is not U-shaped.

Clearly, assuming in addition that all factors are ***normal***, with the expansion path positively sloped, would be sufficient for f to be classical. But neither this nor Assumption F is necessary. Any analysis based on these assumptions is therefore limited in its generality, since it assumes away many valid classical functions.

In conclusion, if the production function is ***nonhomothetic***[19] it is the behavior of the scale elasticity ***along the expansion path*** which determines the shape of average costs and the validity of the function for competitive equilibrium. Analysis of the behavior of the elasticity of scale along rays of equiproportional changes in inputs, or along other paths of variation of inputs, does not yield conclusive results, and may lead to errors.[20]

---

[18] In this simple example, Assumption F and regularity of $f(x)$ hold only locally. But similar examples exist with f regular and Assumption F holding globally, for all $x \gg 0$. See fn. 16.

[19] For $f(x)$ homothetic, the scale elasticity is a function of output alone: $\epsilon=\epsilon(y)$. Hence $\partial\epsilon/\partial y$ is also a function of y only, and is independent of the particular direction of change in inputs.

[20] A typical error is to examine the validity of a functional form by examining the behavior of ϵ along rays, and infer from it (explicitly or implicitly) about the shape of average costs. The Welfare Effects of Spatial Price Discrimination

By William L. Holahan*

In a recent article in this *Review*, M. L. Greenhut and H. Ohta (G-O) demonstrated that a spatial monopolist who adopts a spatially discriminating price would produce a larger output than under a mill price policy. They raise, without elaboration, the possibility that this larger output corresponds to a greater level of net benefits. The purpose of this paper is to examine a model in which the net benefits of both price policies can be measured and to extend the discussion to the case of competition for market areas—called spatial monopolistic competition in location theory (see Martin Beckmann 1968, 1970, 1971).

Section I introduces a model, somewhat simpler than that of G-O, in which the basic result of G-O can be derived and the welfare effects of the two policies can be measured. Here it is found that when there is no significant competition for the firm's market area, spatial price discrimination results in firms producing larger output, serving larger market areas, and promoting greater net benefits than under a mill price policy.

Section II then considers spatial monopolistic competition in which extra normal profits invite invasion of market areas. It is shown that the equilibrium firm output and market area will be smaller under spatial price discrimination than under mill pricing and that if price discrimination is allowed, firms will be forced by free entry to adopt that policy. It is also shown that customers buy more when spatial price discrimination is imposed than under mill pricing, but that they are worse off—greater net benefits are derived under mill pricing.

I. The Basic Model

Consider a simple setting: a linear region of uniform population density v per unit length. Let each customer at a distance r from the firm have a demand given by:

$$q = a - b(P + tr) \tag{1}$$

where q = quantity demanded
P = money price at mill
t = transportation cost per unit distance, and hence
tr = transportation cost facing customers at distance r; and $a, b > 0$.

Also let the cost function of the typical firm be given by:[1]

$$C = mQ + F \tag{2}$$

Let the firm be at the center of a linear market area in which there is a constant density of customers v per unit length. Now equations (1) and (2) can be used to write the expressions for net revenue above fixed cost as a function of r:

$$NR(P, r) = v(P - m)(a - bP - btr) \tag{3}$$

Under price discrimination the object is to maximize $NR(P, r)$ at every distance by solving $\partial NR(P, r)/\partial P = 0$. This price policy is:

$$P(r) = \frac{a}{2b} + \frac{m}{2} - \frac{tr}{2} \tag{4}$$

From (4) we see that the price falls as distance from the firm increases. Substituting (4) into (3) the contribution to net operating revenue as a function of r becomes:

---

* Assistant professor of economics, University of Wisconsin-Milwaukee. I wish to thank Martin Beckmann for helpful comments on an earlier version.

[1] The cost function assumed in (2) above gives rise to economies of scale in production. This is equivalent to assuming that if a firm faces a textbook "U-shaped" long-run average cost (*LAC*) curve it will operate on the downward sloping portion. Beckmann (1968) argues that since costs in a spatial economy equal the sum of production plus transportation costs, "when some cost of plant is fixed . . . economies of scale are always consistent with an optimum scale of plant" (p. 46). In addition, it is often true that an "L-shaped" *LAC* curve is more realistic than the U-shaped curve. For the comparative static results presented here, therefore, the linear total cost curve seems justified.

$$(5)\qquad NR(r:P(r)) = \frac{v}{4b}(a - bm - btr)^2$$

The total profit under price discrimination (πD) is therefore the sum of all these contributions minus fixed cost:

$$(6)\qquad \pi D = 2\int_0^{R_d} \frac{v}{4b}(a - bm - btr)^2 dr - F$$

or

$$(7)\qquad \pi D = \frac{v(a - bm)^2 R_d}{2b} - \frac{v(a - bm)tR_d^2}{2} + \frac{vt^2 bR_d^3}{6} - F$$

where R_d is the radius of the firm's market area, to be derived shortly.

A comparable expression for total profit under mill pricing (πM) can be derived by considering (8):

$$(8)\qquad \pi M = 2\int_0^{R_m} v(P-m)(a-bP-btr)dr - F$$

Equation (8) gives the sum over all locations of the net revenue contributions from sale to customers at each distance r. Here the firm charges the same price to all, regardless of distance. Integrating and maximizing with respect to P gives the profit maximizing mill price:

$$(9)\qquad P = \frac{a}{2b} + \frac{m}{2} - \frac{tR_m}{4}$$

Using (9), equation (8) becomes:

$$(10)\qquad \pi M = \frac{v(a - bm)^2 R_m}{2b} - \frac{v(a - bm)tR_m^2}{2} + \frac{vt^2 bR_m^3}{8} - F$$

The market extremity for a spatial monopolist is that distance at which demand falls to zero due to high total transport costs. Substituting (4) into (1) yields the demand under spatial price discrimination as a function of r:

$$(11)\qquad q_d(r) = \tfrac{1}{2}(a - bm - btr)$$

Setting $q_d(R_d) = 0$ we find the market radius under spatial price discrimination:

$$(12)\qquad R_d = \frac{(a - bm)}{bt}$$

Similarly, substituting (9) into (1) yields demand under mill pricing as a function of r:

$$(13)\qquad q_m(r) = \tfrac{1}{2}(a - bm) + \frac{btR_m}{4} - btr$$

Setting $q_m(R_m) = 0$ we find the market radius under mill pricing:

$$(14)\qquad R_m = \frac{2(a - bm)}{3bt}$$

Profit under the two policies can be compared by substituting (12) and (14) into (7) and (10), respectively:

$$(15)\qquad \pi D(R_d) = \frac{v(a - bm)^3}{6b^2 t} - F > \pi M(R_m) = \frac{4v(a - bm)^3}{27b^2 t} - F$$

Here we see that profit under discriminatory pricing is greater than under mill pricing.

We can also show that the output of the firm is larger under spatial price discrimination than mill pricing. Using (11) we can calculate total output:

$$(16)\qquad Q_d = 2\int_0^{R_d} vq_d(r)dr = v(a - bm)R_d - \frac{vbtR_d^2}{2}$$

Using (12) in (16) we find:

$$(17)\qquad Q_d = \frac{v(a - bm)^2}{bt}$$

Similarly we can calculate total output under mill pricing:

$$(18)\qquad Q_m = 2\int_0^{R_m} vq_m dr = v(a-bm)R_m - \frac{vbtR_m^2}{2}$$

Using (14) in (18) we find

$$(19)\qquad Q_m = \frac{4v(a-bm)^2}{9bt}$$

Comparing (19) and (17) we see that $Q_d > Q_m$. The larger demand from distant customers attracted by the lower spatial price discrimination prices outweighs the smaller demand from nearby customers who pay a higher price under spatial price discrimination. This can be seen more clearly by examining the total price—money plus transportation costs—which customers pay as a function of distance from the production site:

$$(20)\qquad TP = P + tr$$

Using (4) and (9) we can write the expression for TP under spatial price discrimination and mill pricing:

$$(21)\quad TPD = \frac{a}{2b} + \frac{m}{2} + \frac{tr}{2}$$

$$(22)\quad TPM = \left(\frac{a}{2b} + \frac{m}{2} - \frac{tR_m}{4}\right) + tr$$

Here we see that $TPD \lesseqgtr TPM$ accordingly as $r \lesseqgtr R_m/2$. That is, relative to mill pricing, the spatial price discrimination policy imposes a welfare loss on nearby customers in the region $(0, (a-bm)/3bt)$ and results in a welfare gain both on customers in region $((a-bm)/3bt, 2(a-bm)/3bt)$ plus the new customers in region $(2(a-bm/3bt), (a-bm)/bt)$. The price policies are graphed in Figure 1.

Part of what has been shown so far is the basic Greenhut-Ohta result: spatial monopolists employing spatial price discrimination will serve a larger market area, produce a larger output, and make a higher profit than if they employ mill pricing.

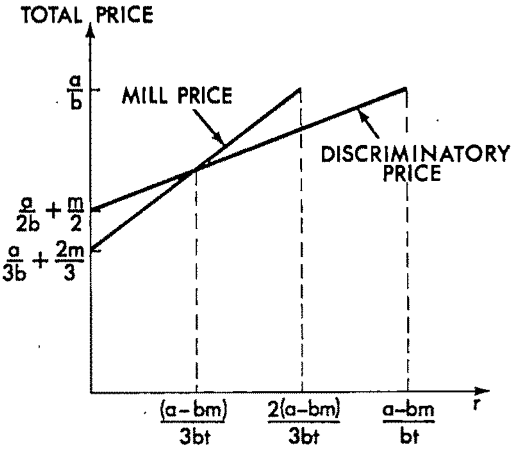

FIGURE 1

We have also seen that there are gainers and losers among the population served, relative to mill pricing. The question arises, how do the two policies compare in terms of a welfare measure? We can address this by using consumers' surplus plus profit as a measure of net benefits. Assuming all customers are alike and using the demand function (1), the consumers' surplus is written:

$$(23)\quad CS = 2\int_0^R \frac{v}{2b}(a - bP - btr)^2 dr$$

Upon substituting (4) into (23) and integrating we get the expression for consumers' surplus under spatial price discrimination:

$$(24)\quad CSD = \frac{v(a-bm)^2 R_d}{4b} - \frac{v(a-bm)tR_d^2}{4} + \frac{vt^2 bR_d^3}{12}$$

Substituting (12) into (24) we get for the discriminatory case:

$$(25)\qquad CSD\left(\frac{a-bm}{bt}\right) = \frac{v(a-bm)^3}{12b^2t}$$

Adding πD and CSD we get the welfare measure under spatial price discrimination

$$(26)\qquad WD = \frac{v(a-bm)^3}{4b^2t} - F$$

Similarly we can compute the net benefits provided under a mill price policy. Substituting (9) into (23) and integrating yields the expression for consumers' surplus under mill pricing:

$$(27)\quad CSM=\frac{v(a-bm)^2R_m}{4b}-\frac{v(a-bm)tR_m^2}{4}+\frac{7vt^2bR_m^3}{48}$$

The level of net benefits provided by mill pricing in the noncompetitive case is the sum of (10) and (27) evaluated at the market radius $R_m=2(a-bm)/3bt$:

$$(28)\qquad WM=\frac{20v(a-bm)^3}{81bt}-F$$

Comparing (26) and (28) we see that spatial price discrimination provides a slightly greater level of benefits. The higher net benefits derived by distant customers under spatial price discrimination, compared to mill pricing, outweigh the loss of nearby customers.

II. The Competitive Case

We can use the equations derived thus far to examine the equilibria arising from the two pricing policies under free entry—invasion of market areas. Letting free entry drive profits to zero, we can use (7) to derive a formula for the equilibrium market size under spatial price discrimination, R_d:

$$(29)\quad \rho\equiv\frac{v(a-bm)^2R_d}{2b}-\frac{v(a-bm)tR_d^2}{2}+\frac{vt^2bR_d^3}{6}=F$$

This is comparable to the equation obtained for the mill price free entry equilibrium market radius R_m found by setting πM in (10) equal to zero:

$$(30)\quad \gamma\equiv\frac{v(a-bm)^2R_m}{2b}-\frac{v(a-bm)tR_m^2}{2}+\frac{vt^2bR_m^3}{8}=F$$

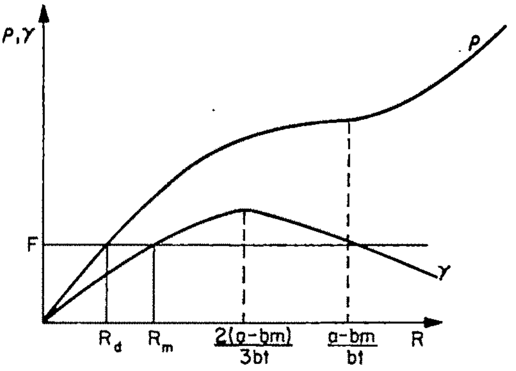

FIGURE 2

Equations (29) and (30) are third degree equations which cannot be readily solved for their roots, but we can show that $R_m>R_d$ by appealing to a geometric argument. Graphing (29) and (30) in Figure 2 we see equilibrium R_m and R_d occur at the intersection of γ and ρ, respectively, and the F line. Since $\gamma<\rho$ for all relevant[2] R, it is clear that $R_m>R_d$. Consulting (16) and (18) we see that $Q_m>Q_d$ since $R_m>R_d$.

It is also clear from (21) and (22) that if spatial price discrimination is allowed, firms will be forced by free entry to adopt it. To see this, let there be a free entry equilibrium under mill pricing. Then by allowing spatial price discrimination we see by (21) and (22) that a firm will be able to undercut a competitor who retains a mill pricing policy at the boundary of their market areas. This will force a competitor to adopt spatial price discrimination in order to offer a matching price at the boundary. Thus the mill pricing equilibrium breaks down. Over time, a new equilibrium will arise in which the region will be served by smaller firms each having a market size given by (29).

---

[2] The distance at which demand falls to zero under the two price policies is the limit of the domain of relevance in Figure 2. As given by (12) and (14) these limits are $R_d=(a-bm)/bt$ and $R_m=2(a-bm)/3bt$. Therefore roots of (29) and (30) which occur beyond those limits are extraneous by economic considerations. Furthermore, for $v(a-bm)^3/6\ b^2t>F>4v(a-bm)^3/27\ b^2t$ firms can survive only if they use the spatial price discrimination policy. We can therefore limit our discussion to $0<R<2(a-bm)/3bt$ and $0<F<4v(a-bm)^3/27\ b^2t$ since these are the ranges in which firms can choose between the price schemes.

We can also see that there will be more output per person under spatial price discrimination because, relative to the mill pricing equilibrium, the increase in the number of firms per area is greater than proportional to the decrease in size of each firm. This can be seen by forming the expression for output per person (QPP):

$$QPP = \frac{Q}{2vR} = \frac{(a - bm)}{2} - \frac{tR}{4} \tag{31}$$

Since $R_m > R_d$ we see from (31) that $QPP_m < QPP_d$.

However, more output per person is not necessarily better. The relevant benefit measure in this spatially extended economy is welfare per area. Dividing (24) and (27) by $2R$, the market area per firm, we can form the expression for consumers' surplus per area under discriminatory pricing ($CSDA$) and mill pricing ($CSMA$), respectively,

$$CSDA = \frac{v(a - bm)^2}{8b} - \frac{v(a - bm)tR_d}{8} + \frac{vt^2bR_d^2}{24} \tag{32}$$

$$CSMA = \frac{v(a - bm)^2}{8b} - \frac{v(a - bm)tR_m}{8} + \frac{7vt^2bR_m^2}{96} \tag{33}$$

Since these equations differ only in the numerical coefficients and not in the parametric coefficients we can normalize the parameters to construct a comparison of welfare per area.[8] Equations (32) and (33) then become

$$CSDA' = \frac{1}{8} - \frac{R_d}{8} + \frac{R_d^2}{24} \tag{32'}$$

$$CSMA' = \frac{1}{8} - \frac{R_m}{8} + \frac{7R_m^2}{96} \tag{33'}$$

Similarly, (29) and (30) can be normalized:

$$\frac{R_d}{2} - \frac{R_d^2}{2} + \frac{R_d^3}{6} = F \tag{29'}$$

$$\frac{R_m}{2} - \frac{R_m^2}{2} + \frac{R_m^3}{8} = F \tag{30'}$$

For every value of F there corresponds a level of net benefits for each price policy. The procedure followed now is to generate the roots of (29′) and (30′) for values of F ranging from zero to 4/27 (the maximum value of F consistent with nonzero profits under mill pricing) and substitute those roots into (32′) and (33′) and compare $CSDA'$ and $CSMA'$. A computer simulation is needed since (29′) and (30′) are third-degree equations and do not yield to algebraic solution.

The roots generated and the level of net benefits as a function of F are given in the Appendix and graphed in Figure 3. It is seen in Figure 3 that mill pricing is superior to

---

[8] By the following manipulations we can see that the result holds for any set of parameter values. Using (29), (30), (32), and (33) note that:

$$CSDA = \frac{F}{4R_d} \quad \text{and,} \tag{a}$$

$$CSMA = \frac{F}{4R_m} + \frac{4vt^2bR_m^2}{96} \tag{b}$$

Hence the inequality: $CSDA \gtrless CSMA$, is equivalent to:

$$\frac{F}{4}\left(\frac{R_m - R_d}{R_mR_d}\right) \gtrless \frac{4vt^2bR_m^2}{96} \tag{c}$$

Now divide (29) by $4R_d$ and (30) by $4R_m$ and subtract and get another expression for the left-hand side of (c):

$$\frac{F}{4}\left(\frac{R_m - R_d}{R_mR_d}\right) = vt^2b\left(\frac{R_d^2}{24} - \frac{R_m^2}{32}\right) - \frac{v(a - bm)t(R_d - R_m)}{8} \tag{d}$$

Using (d) and rearranging, (c) becomes:

$$\left(\frac{R_d^2}{24} - \frac{R_m^2}{32}\right) - \frac{(a - bm)(R_d - R_m)}{8bt} \gtrless \frac{4R_m^2}{96} \tag{e}$$

Since the variables R_m and R_d are measured in distance units of $[(a-bm)/bt]$, it is easily seen that condition (e) is invariant with respect to changes in parameters and hence the welfare comparison in the text holds for all possible parameter sets.

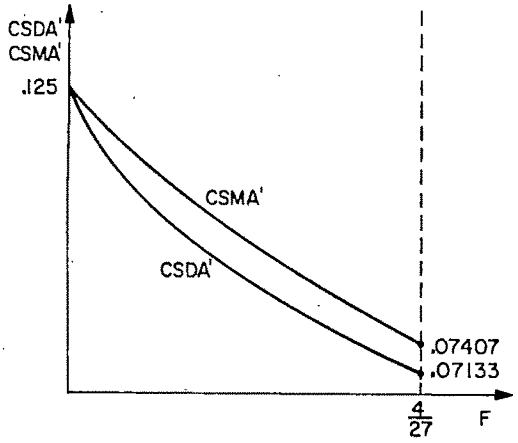

FIGURE 3

spatial price discrimination for all parameter values of F. Therefore, even though the mill pricing policy results in smaller output per person, there is greater benefit per person from mill pricing.

III. Summary

We have found that in regions where competition is insignificant, spatial price discrimination results in larger firms and greater net benefits than a mill price policy. In addition, firms will tend to adopt the better policy since, by using price discrimination to induce distance customers to purchase more, higher profits will be made. Under free entry mill pricing results in larger firms spaced further apart and a smaller output per person. Mill pricing bestows greater net benefits but unregulated firms will be forced by free entry to adopt the worse of the two policies—spatial price discrimination.

Wage Determination, Inflation, and the Industrial Structure: Comment

By WILLIAM A. BOMBERGER*

In a recent article in this *Review*, Stephen Ross and Michael Wachter (R-W) have argued that in an economy consisting of a competitive sector and a partially noncompetitive sector, there should be a positive relationship between the long-run unemployment rate and the long-run inflation rate if that inflation rate is positive, and a negative relationship if the inflation rate is negative. The purposes of this comment are: 1) to point out that this relationship is not the necessary result of the introduction of noncompetitive elements as is claimed by the authors, but depends instead upon the rather curious use of the planning horizon attributed to the R-W noncompetitive firms; and 2) the model faces serious problems with regard to the existence and attainment of stable equilibrium and the congruence of its predictions with past experience.

R-W construct an economy consisting of two sectors. The competitive sector is characterized by nominal wages and prices which can continuously change and a real wage which is fixed. Firms in the noncompetitive sector are capable of changing wages w^a and prices p^a independently but choose to do so only at regular intervals.

Given the perceived market structure facing the noncompetitive firms a choice of

$$(1) \quad w^a = \phi w^c \quad \text{and} \quad p^a = \mu p^c \quad \mu, \phi > 0$$

would maximize profits at any given time. However, once wages and prices are set, they will not be changed until after a certain time interval has passed. Thus, intervening events may alter the market conditions and produce excess product demand or excess labor supply. R-W assume that customer queuing is more costly than working queuing, and that firms are risk averse. This leads firms to attempt to bring about a market position

$$(2) \quad w^a = \phi\psi w^c \quad \text{and} \quad p^a = \mu\psi p^c \quad \psi > 1$$

which hedges against excess product demand.[1]

Had R-W stopped here, their model would have a short-run inflation-unemployment tradeoff, but a long-run "natural" unemployment rate consistent with any inflation rate. However, the noncompetitive firms are assumed to have the curious habit of being interested only in their market position at some specific time τ within their fixed-price interval.

Clearly if at time T the firm wishes to set wages and prices such that (2) will occur at time $T+\tau$ $(0<\tau<1)$, before it can change wages and prices again at time $T+1$, it must anticipate the change in competitive prices and wages in the interval. If the firm anticipates an inflation rate in p^c of $E(\xi)$, it will set

$$(3) \quad \overset{a}{w}_{T} = \phi\psi \overset{c}{w}_{T} e^{-E(\xi)\tau}; \quad \overset{a}{p}_{T+\tau} = \mu\psi \overset{c}{p}_{T} e^{-E(\xi)\tau}$$

so that

$$(4) \quad \overset{a}{w}_{T+\tau} = \phi\psi E(\overset{c}{w}_{T+\tau}); \quad \overset{a}{p}_{T+\tau} = \mu\psi E(\overset{c}{p}_{T+\tau})$$

If $\tau \geq \frac{1}{2}$, a fully anticipated rise in the inflation rate produces a higher average level of w^a/w^c (averaged, that is, over firms with staggered planning intervals). In the R-W model this is accompanied by a rise in the supply of labor to the noncompetitive sector and an increase in long-run unemployment. In other words, if a firm wants to achieve the proper wage premium at time $T+\tau$, a rise in the inflation rate forces the firm to overshoot the wage premium by a greater amount in the period preceding the relevant date and to suffer a larger excess supply in the labor market until that time.

Despite the claim of R-W this result depends in no way upon either the market power of the noncompetitive firms or the fact that such firms prefer excess supply of labor to excess demand for their products.[2] The reader may simply note that allowing $\psi<1$ (i.e., assuming worker queues to be more costly than customer queues) only shifts the long-run Phillips curve. Its shape is unaltered.

---

* Assistant professor of economics, Wayne State University.

[1] As they state in their article: "Hence, the opportunity loss from underestimating the rate of inflation [creating excess product demand] exceeds that of overestimating [creating excess labor supply], and the risk-averse firm will pay a wage premium. This safety factor is measured by the term $\psi > 1$ . . ." p. 680.

The shape of the long-run curve is the result of the use of the fixed-price interval. If one assumes that such firms change prices and wages only on January 1 each year, for example, R-W assume that wages and prices will be set so as to produce the desired market position on, say, Columbus Day,[3] ignoring the larger excess supply of labor which will precede Columbus Day and the excess product demand which may begin sometime thereafter. A more sensible firm might consider its *average* market position over the year and set a target for the *average* values of w^a/w^c. For the wage rate this means:

$$(5)\quad E(w^a/w^c) = \int_0^1 (w^a_{\mathrm{T}}/w^c_{\mathrm{T}+\tau})\,d\tau = w^a_{\mathrm{T}}/w^c_{\mathrm{T}}(1 - e^{-E(\xi)})/E(\xi)$$

Given the market parameters of the firm and their preference for excess supplies of labor, this means the profit maximizing firm will set

$$(6)\qquad w^a_{\mathrm{T}} = w^c_{\mathrm{T}}(1 - e^{-E(\xi)})^{-1}E(\xi)\phi\psi$$

This changes equation (15) of R-W to

$$(7)\qquad w^a(\mathrm{T})/w^c_{\mathrm{T}} = \phi\psi$$

The average relative wage, and hence the equilibrium unemployment rate, no longer depends upon the inflation rate. The model now exhibits a long-run vertical Phillips curve. The C-shaped relationship was, then, generated by the assumption that workers respond to average wage differentials over the period but firms are interested only in their market position at a specific date within the period.[4]

But the difficulties of the model are not limited to the questionable nature of its key assumption. To illustrate another difficulty let us eliminate the assumption of a target date so that (7) represents a condition of long-run equilibrium. Consider an autonomous increase in demand m. Both sectors will attempt to raise wages and prices and will generate a higher inflation rate. As long as $E(\xi)$ remains unchanged, an equilibrium will be reached at a higher inflation rate characterized by a lower average wage premium offered by the noncompetitive firms which is caused by their underestimation of the inflation rate among competitive firms. This lowers the unemployment rate by shortening the worker queue in the noncompetitive sector. This is illustrated by a movement along the short-run Phillips curve from A to B in Figure 1.

However, as a higher inflation rate persists, $E(\xi)$ must rise. The short-run curve then shifts upward and a new short-run equilibrium is maintained at C. The model is now identical with any natural rate model *à la* Phelps, Friedman, etc. As long as the excess demand is not dissipated by the effects of inflation itself (say a reduction in real balances) or by outside forces, a familiar accelerating inflation rate occurs.

Consider now Figure 2, in which the target date optimization has been reinstated. In such a case there exists a point D at which an equilibrium consistent with the increased demand can be attained. However, the time path of inflation and unemployment is the same as in Figure 1. The equilibrium exists but will not be attained. If such a position were attained, its stability would be questionable but one cannot say more without postulating the relationship between infla-

---

[2] They state: "The emergence of an upward sloping long-run Phillips curve has its roots in the assumption that the administered firm finds a customer queue more costly than a worker queue . . ." p. 688.

[3] In order to generate the proper results it is necessary that the appropriate date be at least halfway through the planning period. If the appropriate date was Valentines Day, we would have a reverse C-shaped relationship with the more traditional Phillips curve in the case of positive inflation and its mirror image in the case of deflation. This fact is apparently recognized by the authors although they fail to make explicit use of it.

[4] It might be reasonable for mathematical convenience to approximate a firm's period-long planning in terms of its view of a certain target date within that period. However no such convenience is realized. The target date approximation is more difficult to handle and leads to perverse firm behavior (see fn. 5 below).

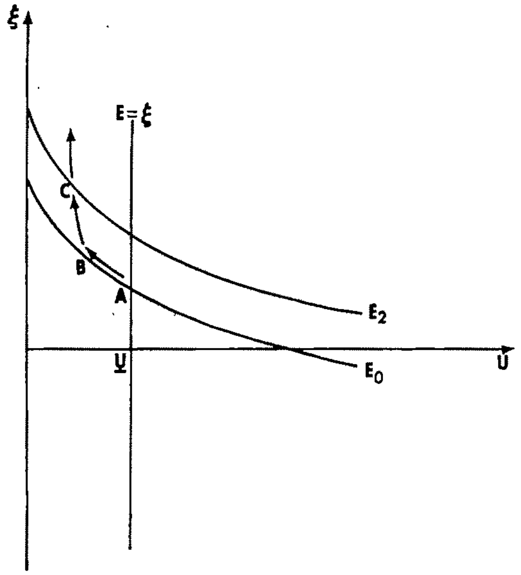

FIGURE 1

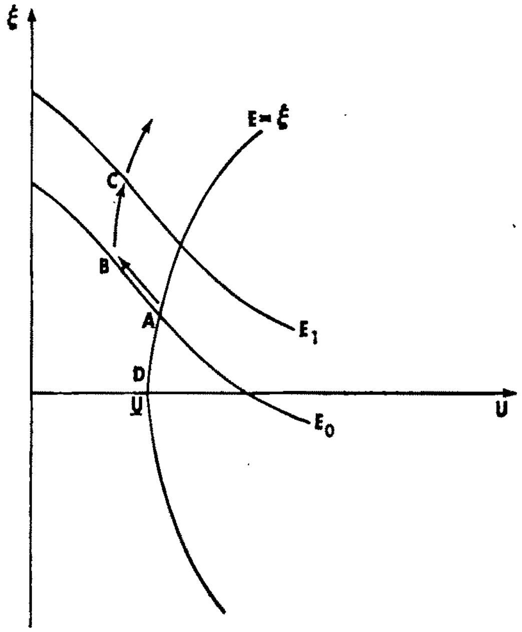

FIGURE 2

tion and excess demand in the competitive sector.

Suppose the R-W economy is in a long-run equilibrium at A with a 5 percent unemployment rate and a 4 percent inflation rate. Suppose further that product demand is increased to such a degree that the new equilibrium unemployment rate at D will be 4 percent. When the economy has again reached equilibrium, the labor queue in the noncompetitive sector must be shorter. Hence, the average wage premium in that sector, w^a/w^c, must be lower. However, according to R-W $\phi'(m)$ is positive—an increased demand for their product induces these firms to raise their wage premium *on the target date.* These two facts can be reconciled if the inflation rate falls sufficiently.

At sufficiently lower rates of inflation the noncompetitive firms will accept a lower average relative wage in order to achieve a higher relative wage on the target date.[5]

To examine the usefulness of this effect assume that in order for equilibrium employment to increase by 1 percent, a 1 percent reduction in the average wage premium is necessary. Further assume that a 1 percent increase in demand convinces the noncompetitive firms to increase their wage premium by 1 percent (ϕ increases by 1 percent). By equation (15) of R-W $h(\xi)$ must fall by 2 percent to achieve equilibrium. Using the R-W formula for $h(\xi)$ (in which Columbus Day falls on July 1, $\tau=\frac{1}{2}$), one finds that ξ must fall to -64 percent to restore equilibrium. Such a result implies a Phillips curve so close to the vertical as to be empirically indistinguishable from it. Except, of course, that one travels the "wrong way" along this curve. The enormous deflation must be generated by an increase in demand. If such a model describes our present economy the recent acceleration of inflation can be attributed to insufficient demand.[6]

---

[5] The fact that a desire to increase the relative wage leads to a decrease in its average value is paradoxical. The fact that this lower average relative wage is found acceptable to the firms in this sector illustrates the perverse behavior such a target date "approximation" can generate.

[6] Clearly, different numbers would have produced different results. However, the numbers above are not unreasonable. Unless the labor supply to competitive firms increases significantly in response to truly microscopic changes in wage differentials even as the labor queue in the noncompetitive sector is being shortened, the long-run tradeoff will be extremely steep.

Wage Determination, Inflation, and the Industrial Structure: Reply

By STEPHEN A. ROSS AND MICHAEL L. WACHTER*

William Bomberger in his comment on our recent article raises three points. All are related to our long-run tradeoff between unemployment and inflation. His first point is that our C-shaped Phillips curve is not dependent on noncompetitive forces, as we claim to be the case, but rather is related to our "rather curious use of the planning horizon." His second point is that our long-run model faces serious stability problems. His third point is that our analysis does not yield results which are congruent with the economy's experiences.

Bomberger's first point is incorrect. He seems to believe that the size of the markup variable ψ captures all of the noncompetitive elements in our model. This is not the case. Although the ψ variable is unique to the noncompetitive sector, measuring the safety factor or the risk aversion of the noncompetitive firm, it is not the only factor which distinguishes the noncompetitive sector.

Rather, the main impact of the noncompetitive sector is in introducing the timing or planning period problem. Whereas competitive firms may be viewed as setting wages and prices continuously, the noncompetitive firm acts discontinuously. This creates a planning period over which the noncompetitive firm maintains a fixed wage and price strategy. We also make the important assumption that the firm is more concerned about a customer queue than a labor queue. The result is that it will set a wage premium so as to have a labor queue in the "bulk" of the planning period. At the extreme where it views a customer queue as prohibitive, this will mean setting a wage premium sufficient to insure a labor queue *throughout* the period. The identical result can be obtained by assuming that the elasticity of the supply of labor to the noncompetitive firm is larger than the elasticity of the derived demand for labor. Both assumptions—that the firm is more concerned with a customer than with a labor queue and that the supply elasticity is greater than the demand elasticity—seem to us to be theoretically viable and well established in the empirical literature.

Since Bomberger views ψ as representing the noncompetitive elements in the model, he does not appreciate the role played by the fixed planning period. This leads him to suggest that a more straightforward way of dealing with the planning period is for the firm to consider its *average* market position. This, however, would eliminate one of the basic assumptions of our analysis. Since the noncompetitive firm is more concerned with a customer than a worker queue, it looks toward the *end* of the planning period in setting wages and prices.

Bomberger observes that when firms look to the middle of the period, setting a wage premium sufficient to have a labor queue in the first half of the period and a customer queue in the second, the numerical elasticity of the long-run Phillips curve is quite low. As he verifies in equation (5) by using a period average (ignoring discounting), the wage markup is, in fact, exactly independent of the inflation rate. This is just what one would expect. We analyzed the midpoint case precisely because it gives a lower bound to the slope of the long-run tradeoff. Our point was and still remains, however, that noncompetitive firms aim *beyond* the midpoint.

As for the numerical elasticity, in the extreme where only a labor queue is tolerable, the noncompetitive firm sets $E=e^{\zeta}$ and the aggregate wage premium of our equation (15) is proportional to

$$e^{\zeta} g(\zeta) = \frac{1}{\zeta}(e^{\zeta} - 1) \tag{1}$$

---

* Professor of economics and associate professor of economics, respectively, University of Pennsylvania.

It can be shown that this roughly implies that a 1 percent decline in the inflation rate lowers the relative wage premium by $\frac{1}{2}$ percent. The elasticity of the Phillips curve then depends upon the elasticity of the interindustry labor supply with respect to relative wages. If this elasticity is high, as seems likely to us, then our C-shaped Phillips curve will be quite different from the traditional vertical long-run curve.

Bomberger's second point concerns the disequilibrium behavior of the model. In an earlier version of the paper we developed some of the analytics of this, but the present version contained only the verbal analysis of Section V. We chose not to do formal disequilibrium analysis for two reasons, both of which come to the same thing—it is very difficult to do it right. On the one hand, it requires a sensible mechanism for the formation of expectations in disequilibrium and it did not appear possible to us to easily solve such an important matter. Second, as we observed, a model with an institutional structure will in profound disequilibrium undergo dynamic institutional responses to the inflation rate. One simple and relevant example is the introduction, as inflation increases, of escalator clauses in collective bargaining contracts. This type of institutional response also merits a separate study.

Bomberger's observation that the Phillips curve is unstable, in the sense that movement along the curve in a dynamic context is impossible, should not be surprising. The model does not imply, however, as Bomberger suggests, that an increase in aggregate demand would require a deflation in prices. Suppose that we are initially in equilibrium at a point where a short-run Phillips curve intersects the C-shaped curve. Our disequilibrium analysis (with unchanging expectations and institutions) indicates that an increase in aggregate demand, while initially increasing the inflation rate, will cause the rate to undershoot the short-run Phillips curve and then to move towards that curve. It is likely that the dynamic movement will go beyond the short-run curve, generating a spiraling inflation. That a new static equilibrium may not be reached along the short-run Phillips curve is not disturbing. Since aggregate demand is being fixed beyond full employment, expectations should adjust upward, shifting the short-run curve in the same direction—towards an ever increasing rate of inflation. Observed behavior and the empirical Phillips curve, however, are generated, not by a fixed unemployment rate, but rather by a cyclically changing rate. The dynamic behavior implied by our analysis can generate this type of observed behavior. The short-run downward sloping Phillips curve is a statistical relationship and should not be treated as a static equilibrium relationship.

On the other hand, if one feels that stability is a necessary feature of a dynamic model, then one can add other variables to our analysis to dampen disequilibrium behavior. Our model explicitly abstracts from certain traditional Phillips curve elements in order to concentrate on the impact of introducing a noncompetitive sector with a fixed planning period.

Both our C-shaped Phillips curve and the neoclassical vertical curve are unstable in that any government attempt to reduce and maintain the unemployment rate below its equilibrium level will lead to accelerating inflation. A difference between the two, however, is that in our model, once the government decides to return to full employment, it finds that the equilibrium unemployment rate is higher than it was before the demand-pull inflation was started. (This, of course, assumes that inflationary expectations have adjusted upward.) Whether or not society actually observes this adverse long-run tradeoff as mentioned above, depends upon the nature of institutional adjustments to inflation in the long run. Our own guess is that such an adverse tradeoff might well be expected.

Finally, Bomberger charges that our model does not describe actual behavior. This comment is made in the context of his incorrect supposition that our model requires an increase in aggregate demand to lead to a deflation. If his description of our model were correct, we would agree that it is not in tune with actual events. Fortunately, but not by accident, our model does not make such predictions. We believe that our model does have relevant implications for the inflation problem. In particular, the planning period effect provides a theoretical justification for lags of adjustment longer than that found in neoclassical, competitive models. As a consequence, inflation may not easily respond to government-induced cycles geared to the four-year national election sequence. Furthermore, the distinction between competitive and noncompetitive sectors gives rise to variation in interindustry wages and prices which may appear to be cost-push inflation when, in fact, it is only a lagged response to demand-pull pressure. This traces out a complex pattern of demand-pull inflation where in the initial period of falling unemployment, the competitive industries lead in raising wages and prices. In the second stage, a period of steady or rising unemployment and catch-up wage and price differentials, the noncompetitive industries attempt to reestablish their traditional differentials.

Pitfalls in Financial Model Building: A Clarification

By GARY SMITH[*]

In their well-known "Pitfalls" paper, William Brainard and James Tobin advocated "a 'general disequilibrium' framework for the dynamics of adjustment to a 'general equilibrium' system." The Pitfalls framework has subsequently been widely used in the construction of flow of funds models of financial markets. The Brainard-Tobin paper has also elicited notes from Mark Ladenson and Kevin Clinton in this *Review* which attempt to interpret and elaborate upon the Pitfalls model. However, these authors seriously misinterpret the model and seemingly obscure rather than extend the Pitfalls framework in a maze of unnecessary mathematical techniques and notation.

Ladenson and Clinton both attempt to work with linearly dependent explanatory variables whose coefficients are not identified and cannot be meaningfully interpreted. Clinton uses this indeterminacy to provide a superficial counterexample to a Brainard-Tobin argument. Ladenson, on the other hand, discusses two (of many possible) sets of "expedient" parameter restrictions which will allow him to assign values to all of the coefficients of the linearly dependent variables. He believes that estimation of the model necessitates substantive behavioral assumptions, whereas in fact the elimination of a redundant explanatory variable alters only the appearance of the model and the interpretation of individual coefficients.

In addition to discussing the errors of Clinton and Ladenson, this paper will demonstrate the simplicity with which adding up constraints can be derived, the relationship between the form of a model and the interpretation of its coefficients, and how the parameters might be estimated subject to adding up constraints. In Section I the Pitfalls model is compared with the Clinton-Ladenson formulation; Sections II and III concern the respective details of the Clinton and Ladenson articles; and estimation procedures are discussed in Section IV.

I

All of the authors consider a portfolio model in which desired asset shares depend linearly upon the competing rates of return and other explanatory variables:

$$\frac{a_i^*}{w} = b_{i0} + \sum_{j=1}^{q} b_{ij} r_j \qquad i = 1, \ldots, n \tag{1}$$

where a_i is the actual holding of the ith asset, a_i^* is the desired holding of the ith asset, r_j is the jth rate of return or other explanatory variable, and w is equal to the sum of the a_i.

If, as the authors assume, desired holdings sum to available funds ($\sum_i a_i^* = w$) for all values of the explanatory variables, then

$$1 = \sum_{i=1}^{n} \frac{a_i^*}{w} = \sum_i b_{i0} + \sum_{j=1}^{q} \left(\sum_i b_{ij} \right) r_j$$

Clearly this equation can hold for all values of r_j if and only if

$$\sum_i b_{i0} = 1 \qquad \sum_i b_{ij} = 0 \qquad j \neq 0$$

That is, if all changes in asset value are included in w, then a change in any desired asset share must be compensated by offsetting changes in the remaining shares, and an increase in funds must be fully accompanied by an increase in desired holdings.

All of the authors allow actual holdings to differ from desired shares and assume that holdings will adjust in response to portfolio disequilibria. Brainard and Tobin pointed out that the common specification in which each asset adjusts solely to its own discrepancy between this period's desired and last period's actual holdings

$$\Delta a_i = \epsilon_i [a_i^* - a_i(-1)] \tag{2a}$$

---

[*] Cowles Foundation, Yale University. My research in this area has been supported by grants from the National Science Foundation and the Ford Foundation.

is likely to result in inconsistent or unintentionally implausible behavior since each of these assets is reacting to an incomplete description of the portfolio disequilibria.[1]

The danger of inconsistency arises if specification (2a) is adopted for all n assets. In this case, using $\Delta w = \sum_i [a_i^* - a_i(-1)]$, we have

$$\Delta w = \sum_i \Delta a_i = \sum_i \epsilon_i [a_i^* - a_i(-1)]$$
$$= \epsilon_k \Delta w + \sum_{i \neq k} (\epsilon_i - \epsilon_k)[a_i^* - a_i(-1)]$$

This equation can hold for all potential disequilibria situations if and only if $\epsilon_i = 1$ $i = 1, \ldots, n$. That is, consistency in a pure linear own-adjustment model requires that actual holdings adjust fully so as to always coincide with desired holdings. If some of the ϵ_i are instead allowed to assume values other than 1, then either desired or actual holdings will be inconsistent with available funds for some values of the explanatory variables.

A more frequent practice is to specify own-adjustment equations (2a) for an incomplete list of assets, say for $i = 1, \ldots, q < n$. In this case, the consistency requirement can be used to residually derive the implicit specification of the adjustment equation for the remaining assets as a group,

$$\Delta\left[\sum_{q+1}^{n} a_i\right] = \Delta w - \sum_{1}^{q} \Delta a_i$$
$$= \left[\sum_{q+1}^{n} a_i^* - \sum_{q+1}^{n} a_i(-1)\right]$$
$$+ \sum_{1}^{q} (1 - \epsilon_i)[a_i^* - a_i(-1)]$$

Thus the residual collection of assets implicitly adjusts quite differently from the explicitly specified assets. In particular, the residual collection fully adjusts to its own discrepancy and passively absorbs any funds which are not immediately shifted in accord with desired holdings of any of the assets with explicit adjustment equations. This model could conceivably describe some group's actual behavior. In practice, however, assets are usually included in the residual category not for theoretical reasons, but rather because the model builder is not immediately interested in these items. As a consequence, the specification usually appears to be inadvertant and implausible due to the illiquid nature of the residual assets. One Pitfalls moral is thus that the residual specification should always be directly checked since any inadequacy in this equation must be due to inadequacies in the explicit equations.

To avoid these problems, Brainard and Tobin advocated having each asset adjustment depend upon a complete description of the disequilibria in the portfolio. Ladenson and Clinton instead attempt to work with explanatory variables which overdescribe the portfolio disequilibria:

$$\text{(2b)} \quad \Delta a_i = \sum_{j=1}^{n} \epsilon_{ij}[a_j^* - a_j(-1)] + f_i \Delta w \qquad i = 1, \ldots, n$$

The interpretation of the parameters in this specification is completely arbitrary since the explanatory variables are linearly dependent

$$\text{(3)} \qquad \sum_j [a_j^* - a_j(-1)] = \Delta w$$

The coefficients of these variables consequently cannot be meaningfully interpreted nor empirically identified since no variable can change without the remaining variables also changing in any of an infinite number of ways to maintain the balance sheet identity. There is thus an infinite variety of values for the parameters of (2b) which are consistent with any observed behavior, and each individual parameter is meaningless in that any value is consistent with a particular unique behavioral specification.

A portfolio disequilibrium is fully described by any n of the $n+1$ variables in (2b) and all information relevant to an adjustment model is contained in n such variables. The assignment of specific values to n associated parameters will consequently uniquely describe the behavioral response of a particular asset holding in all possible portfolio situations. It does not require behavioral assumptions to select n variables that will describe the disequilibria, and the specific n variables that are used in the adjustment equations do not constrain behavior in any way. The choice of variables will of course define the interpretation of the individual associated coefficients, but any particular representation can be uniquely rewritten in terms of the coefficients of any other n selected variables.

---

[1] Similar arguments apply when some desired asset shares are assumed to depend upon only a subset of the explanatory variables.

Rather than simply choosing n variables to describe the disequilibria, a Pitfalls model could be formally constructed by substituting the identity (3) into the Clinton-Ladenson model (2b) in order to eliminate a redundant variable. Two of the more popular forms of the Pitfalls model will be illustrated here.

If Δw is eliminated from (2b), then the model can be written as

$$(3') \quad \Delta a_i = \sum_{j=1}^{n} (\epsilon_{ij} + f_i)[a_j^* - a_j(-1)] = \sum_{j=1}^{n} \theta_{ij}[a_j^* - a_j(-1)]$$

The adding up restrictions can be directly derived from

$$\Delta w = \sum_i \Delta a_i = \sum_i \sum_j \theta_{ij} \cdot [a_j^* - a_j(-1)] = \sum_i \theta_{ik}\Delta w + \sum_{j\neq k} \sum_i (\theta_{ij} - \theta_{ik}) \cdot [a_j^* - a_j(-1)]$$

This equation can hold for all possible discrepancies if and only if $\sum_i \theta_{ij} = 1, \ \forall j$. A coefficient θ_{ij} should be interpreted as the partial effect on holdings of the ith asset of a unit increase in desired holdings of the jth asset accompanied by an equal increase in Δw (since one discrepancy is increasing while the remaining discrepancies are held constant). The adding up restrictions state that such an increase in funds must be fully absorbed in the portfolio.

An alternative form of writing the Pitfalls model can be obtained by instead eliminating the kth discrepancy from (2b):

$$(3'') \quad \Delta a_i = \sum_{j\neq k} (\epsilon_{ij} - \epsilon_{ik})[a_j^* - a_j(-1)] + (f_i + \epsilon_{ik})\Delta w = \sum_{j\neq k} \phi_{ij}[a_j^* - a_j(-1)] + h_i \Delta w$$

The adding up restrictions follow from

$$\Delta w = \sum_i \Delta a_i = \sum_{j\neq k} \left(\sum_i \phi_{ij} \right) \cdot [a_j^* - a_j(-1)] + \left(\sum_i h_i \right) \Delta w$$

This can always hold if and only if

$$\sum_i \phi_{ij} = 0, \quad j \neq k \qquad \sum_i h_i = 1$$

Here the explicit coefficients ϕ_{ij} should be interpreted as the partial effect on holdings of the ith asset of desiring to hold one unit more of the jth asset and one unit less of the kth asset. Since Δw is held constant, the adding up restrictions require that any increases in asset holdings must be fully offset by decreases in other holdings. The h_i represents the partial effect of an increase in Δw which the sector desires to hold as the kth asset; the total portfolio will consequently expand by one unit.

The representations (3′) and (3″) are equivalent characterizations, and unique parameter values could be assigned in either case which would identically describe behavior in all portfolio situations. Specifically, the variables in (3′) could be rearranged as

$$\Delta a_i = \sum_{j=1}^{n} \theta_{ij}[a_j^* - a_j(-1)] = \sum_{j\neq k} (\theta_{ij} - \theta_{ik})[a_j^* - a_j(-1)] + \theta_{ik}\Delta w$$

Since this is the same form as (3″), it follows that

$$\phi_{ij} = \theta_{ij} - \theta_{ik}, \quad j \neq k \qquad h_i = \theta_{ik}$$

is necessary and sufficient to insure identical behavior no matter what the values of the explanatory variables. That is, one does not need to make behavioral assumptions in order to rearrange the explanatory variables. Note also that rearranging the variables and redefining the coefficients only rearranges the basic adding up restrictions.

II

After assuming that $\sum_i \epsilon_{ij}$ is constant over j, Clinton proves that

$$\sum_i (\epsilon_{ij} + f_i) = \sum_i \theta_{ij} = 1, \quad \forall j$$

is sufficient to insure adding up in adjustment model (2b). Completely ignoring the linear dependency in this model, he then offers the case

$$\epsilon_{ij} = \begin{cases} 1 - \sum_i f_i, & i = j \\ 0, & i \neq j \end{cases}$$

as a counterexample to Brainard and Tobin's statement that "If no cross-effects were allowed in the explicit equations of adjustment . . . , then the counterparts of all the own-adjustments specified would be loaded into the implicit adjustment equation for [the omitted assets]" (p. 106).

This statement in the Pitfalls paper follows a summary argument against own-adjustment equations such as (2a), the details of which I've given above, and refers to the consequences of omitting cross-effects from the Pitfalls model when written in the form (3″). Clinton's example applies to a different set of parameters and, in light of the arbitrariness of the parameter values in his equations, is neither surprising nor interesting.

What Clinton's example does illustrate is that one must be careful when discussing coefficients (such as "cross-effects") to specify which variables are being held constant. To be meaningful, Clinton's example has to be rewritten in terms of identifiable coefficients.

If, for instance, his example is written in the form of (3′), then

$$\Delta a_i = \left(1 - \sum_j f_j + f_i\right)[a_i^* - a_i(-1)] + \sum_{j \neq i} f_i [a_j^* - a_j(-1)]$$

The cross-effects (f_i) here specify that when one has a unit increase in available funds (w) accompanied by a unit increase in desired holdings of the jth asset, how much of these funds will go into other asset positions. Clinton has not eliminated these cross-effects, and indeed he could not eliminate them without assuming complete adjustment, $a_i = a_i^*$.

If Clinton's example is instead rewritten in the form (3″) that is used throughout the Pitfalls paper,

$$\Delta a_i = \left(1 - \sum_i f_i\right)[a_i^* - a_i(-1)] + f_i \Delta w, \qquad i \neq k$$

$$\Delta a_k = \sum_{j \neq k} - \left(1 - \sum_i f_i\right)[a_j^* - a_j(-1)] + \left(f_k + 1 - \sum_i f_i\right)\Delta w$$

The cross-effects now specify that when one wishes to switch 1 unit from asset k to asset j, how much will be put into asset i ($\neq j$). Instead of contradicting Brainard and Tobin, Clinton's example directly and completely confirms their statement. Precisely as Brainard and Tobin wrote, leaving cross-effects out of all but the kth equation necessitates cross-effects in this residual equation which fully offset the own-effects in the other equations. And cross-effects cannot be absent from all of the equations without eliminating the own-effects, $\Delta a_i = f_i \Delta w$.

In summary Brainard and Tobin are correct in their criticism of own-adjustment equations (2a) and in their discussion of the consequences of setting the cross-effects of model (3″) equal to zero. A similar argument has been made here against equating to zero the cross-effects of model (3′). None of this rules out someone arbitrarily calling some other parameters "cross-effects" and then assigning them a value of zero.

III

In contrast, Ladenson recognizes the linear dependency in the explanatory variables when he substitutes (1) into (2b) for estimation purposes

$$(4)\ \Delta a_i = \left[\sum_{j=1}^{n} \epsilon_{ij} b_{j0}\right] + w \sum_{h} \left[\sum_{j=1}^{n} \epsilon_{ij} b_{jh}\right] r_h w - \sum_{j=1}^{n} \epsilon_{ij} a_j(-1) + f_i \Delta w$$

where $w - \sum_{j=1}^{n} a_j(-1) = \Delta w$.

Although the coefficients can consequently not be uniquely estimated, Ladenson is nevertheless determined to assign values to all of them so that he may calculate estimates for all of the parameters in (1) and (2b). He therefore views the necessary elimination of a linearly redundant explanatory variable from his estimation equation (4) as an "expedient" parameter restriction with behavioral implications. He thus asserts that the elimination of w from (4) ". . . involves the assumption that assets adjust instantaneously to a change in wealth," whereas if Δw is eliminated ". . . we assume that such adjustment occurs with a distributed lag" (1973, p. 1006).

It is of course always possible to impose parameter constraints which alter the model; Ladenson (1971) demonstrates this by resorting to the expedient of setting $b_{j0} = 0$ for all j, even though this violated the consistency requirement that $\sum_j b_{j0} = 1$. However, it is certainly not necessary to impair the model in order to estimate it, and eliminating w, Δw, or $a_k(-1)$ from (4) in truth has no effect upon the model beyond a simple rearrangement of the identifiable parameters.

It was demonstrated above that there are a variety of equivalent and uniquely related ways in which the Pitfalls adjustment equations can be written; it will now be shown that there are similarly a variety of equivalent and uniquely related ways of writing the corresponding Pitfalls estimation equations. In both cases, the Ladenson alternative is to work with linearly dependent variables and unidentifiable parameters; and in both cases it is the elimination of a redundant variable rather than a behavioral assumption that is required to obtain identifiable parameters.

The substitution of (1) into form (3′) of the Pitfalls adjustment equations yields the estimation equation

$$(5a)\quad \Delta a_i = \left[\sum_{j} \theta_{ij} b_{j0}\right] w + \left[\sum_{h} \left[\sum_{j} \theta_{ij} b_{jh}\right] r_h\right] w - \sum_{j} \theta_{ij} a_j(-1)$$

This is indistinguishable from Ladenson's estimation equations (4) when Δw is eliminated. Behavioral restrictions were not needed to derive (3′) from Ladenson's (2b), and are consequently not needed to eliminate Δw from Ladenson's (4).

There are clearly an infinite number of equivalent ways in which (5a) could be rewritten. For example, substituting for $a_k(-1) = w - \sum_{j \neq k} a_j(-1) - \Delta w$ yields this arrangement of explanatory variables

$$(5b)\quad \Delta a_i = \left(\sum_{j} \theta_{ij} b_{j0} - \theta_{ik}\right) w + \sum_{h} \left(\sum_{j} \theta_{ij} b_{jh}\right) r_h w - \sum_{j \neq k} (\theta_{ij} - \theta_{ik}) a_j(-1) + \theta_{ik} \Delta w$$

This is Ladenson's (4) with $a_k(-1)$ eliminated, which could also be directly derived by substituting (1) into (3″) with the correspondence between the parameters again defined by

$$\phi_{ij} = \theta_{ij} - \theta_{ik}, \quad j \neq k \qquad h_i = \theta_{ik}$$

Since (3″) is equivalent to (3′), it follows that deleting $a_k(-1)$ from Ladenson's (4) is equivalent to deleting Δw.

Alternatively, substituting in either (5a) or (5b) for $w = \Delta w + \sum a_j(-1)$ yields yet another equivalent rearrangement of the variables which this time is indistinguishable from Ladenson's (4) with w eliminated.

All of these cases (and all alternative linear rearrangements of the variables and parameters) are just different ways of writing the same model. If one is careful, the form in which the model is written has absolutely no behavioral implications. In particular, irrespective of whether w, $a_k(-1)$, or Δw is eliminated from (4) and no matter how the resultant linearly independent variables are juggled, the final equations will be equivalent to form (5a), and the coefficients of the rearranged variables will be uniquely related to the parameters of (5a). Indeed, it would be very strange if one were only happy with the model when the variables were arranged in a particular way; again we have the Pitfalls moral that explicit representations are no more important than implicit ones.

IV

Single equation ordinary least squares (*OLS*) parameter estimates will generally obey adding up restrictions if the regressors are the same in each equation and if some linear combination of the regressors is always equal to the sum of the regressands.[2] This can be seen directly by writing an estimation equation as

$$\begin{array}{ccccccc} a_i & = & X & \cdot & \beta_i & + & \epsilon_i \\ T\text{x}1 & & T\text{x}p & & p\text{x}1 & & T\text{x}1 \end{array}$$

where we have (possibly) rearranged X so that the first regressor is

$$x_1 = \sum_{i=1}^{n} a_i$$

The sum across equations of the *OLS* parameter estimates are the elements of the column vector

$$\sum_{i=1}^{n} \hat{\beta}_i = \sum_i (X'X)^{-1}X'a_i = (X'X)^{-1}X' \sum_i a_i$$

which is what would result from a regression of $\sum a_i$ on X. The squared residuals for that regression are minimized (are equal to zero) when the coefficient of x_1 is one and all other coefficients are zero.

For *OLS* estimation of the model considered here, the Gauss-Markov Theorem implies that linearly rearranging the explanatory variables in (5a) will not affect the forecasts nor the implicit estimates of any estimatable parameters. In particular, the implicit estimates of the coefficients of (5a) do not depend upon whether w, Δw, or $a_k(-1)$ is deleted from Ladenson's (4). Thus, Ladenson's alleged behavioral constraints are just awkward ways of eliminating a redundant variable and differ only in providing different arbitrary estimates of uninteresting parameters.

In considering *OLS* estimates of the identified structural parameters, it consequently suffices to consider the single case of using the estimation equations (5a) to estimate the parameters of the Pitfalls model (1) and (3'). Rewriting (5a) in obvious matrix notation,

$$a = \theta \cdot B_0 \cdot w + \theta \cdot B \cdot rw + (I_n - \theta)a(-1) + \epsilon$$

(where a is nx1, θ is nxn, B_0 is nx1, B is nxq, and r is qx1). The column elements of the estimates $\widehat{\theta B_0}$ will sum to one and the elements of $\widehat{\theta B}$ and $(\widehat{I-\theta})$ will sum to zero. The column elements of $\hat{\theta} = (\widehat{I-\theta}) + I$ will thus sum to one as desired. The elements of $\hat{B}_0$ and $\hat{B}$ will also sum correctly, since it can be easily shown that the column sums for any matrix $Z = \theta^{-1}(\theta Z)$ will be the same as the column sums of θZ if the columns of θ sum to one.

It is worth noting that hypothesis tests of any coefficients or combinations of coefficients are also invariant to the way in which the equations are written for estimation purposes. However, the usual computer output provides t-statistics for testing the null hypotheses that the explicitly estimated parameters are equal to zero. If one is in the (dubious) habit of imposing zero constraints whenever these are unrejected by the data, then the form in which the equations are written may affect the final estimates if one allows this arbitrary choice to define the subset of possible hypotheses that will be tested. This is of course not a limitation of the model but rather a well-known drawback to mechanically using hypothesis tests for decision-making purposes.

Turning to the question of more complex estimation methods, the automatic imposition of adding up constraints obviously extends to a variety of single equation methods, such as the use of instrumental variables and semi-first differences if and only if the instruments used for each variable and the autoregressive parameters do not vary across equations. It will also remain true that the properly interpreted estimates are independent of the particular linearly dependent variable omitted from (4) and of any subsequent rearrangement of the variables.[8]

---

[2] Ladenson incorrectly states that it is necessary and sufficient that all lagged endogenous variables appear in all equations.

For the class of feasible Aitken generalized least squares system estimators, we will generally have to delete one equation (since the disturbances must sum to zero) and calculate the parameter estimates for this residual equation from the adding up constraints. Fortunately Alan Powell has shown that the estimated coefficients do not depend upon the equation chosen for deletion. In addition, it is well known that such system estimates will be identical to the single equation estimates on which they are based if the final step in the single equation method is the *OLS* regression of equations in which the right-hand side variables do not vary across equations.

The likelihood that the effective dimensionality of the data will be much less than the number of parameters is a persuasive argument for the imposition of a priori parameter restrictions. If one does specify the coefficients associated with a particular variable in every equation, then the single equation methods discussed above will continue to automatically impose the adding up constraints, and the estimated parameters will be identical to the ones that would result from an Aitken procedure. If the parameters are not specified in every equation, then one can enforce the adding up constraints with a stacking procedure or with a Lagrangian modification of the Aitken method (see the discussion by Gordon Sparks for example). If one has useful information about the reliability of the parameter restrictions then a Bayesian or mixed estimation method might be of interest (see Smith and Brainard for example). Unfortunately, all of the non-single equation methods typically involve formidable computational difficulties and the possibility of serious rounding errors.

[8] With instrumental variables, this conclusion requires that all predetermined variables in the equation be included in the list of instruments. We can then view all of the explanatory variables as being regressed upon a common list of regressors. By the earlier adding up proof, forecasts of linear combinations of the explanatory variables will then equal linear combinations of the forecasts of the individual explanatory variables.

Buyer's Prices, Seller's Prices, and Price Flexibility: Comment

By DOUGLAS R. BOHI AND GERALD W. SCULLY*

Recently, the controversy over the administered-price thesis has been renewed with the publication in a book by George Stigler and James Kindahl of a new set of industrial price indexes developed under the auspices of the National Bureau of Economic Research. The National Bureau (*NB*) price indexes are based upon contract prices paid by the buyer. In contrast, the Bureau of Labor Statistics (*BLS*) price indexes employ price quotations or price lists obtained from the seller. Stigler and Kindahl conclude that the *NB* price indexes reveal a significantly different pattern of price behavior from the *BLS* indexes, particularly in the behavior of short-run movements, where the *NB* index changes more often and more smoothly than the *BLS* index.

Furthermore, Stigler and Kindahl employ these buyer-based price indexes to test their version of the administered-price thesis "... that contractions in business lead to no systematic reduction of industrial prices, and ... expansions in business may only tardily lead to price increases" (pp. 7–8). They find that the new commodity price indexes move in response to general business activity and that there is "no evidence here to suggest that price rigidity or 'administration' is a significant phenomena" (p. 9).

In contrast, Gardiner Means recently reexamined the *NB* price data and concluded "... that the new data overwhelmingly support the administered-price thesis; ... and that the new data do not support the report's conclusion that the prices in its sample show a tendency to move with the business cycle" (p. 292).

There are two principal testable hypotheses which emerge from this important controversy. First, there is the question whether the *NB* and *BLS* price indexes are actually different, and, secondly, there is the issue of whether industrial prices respond to market changes over the business cycle or whether they are in fact administratively determined. Both issues are concerned with the nature of the variance of industrial prices. Both the Stigler and Kindahl and the Means studies have analyzed the variance of industrial prices solely within the time domain.

To establish the dissimilarity of the *NB* and *BLS* price series, Stigler and Kindahl used the simple correlation coefficient of unlagged first differences in the logarithms of the indexes over frequency intervals ranging from one month to one year. To test the administered-price thesis, both Stigler and Kindahl and Means examined the average price change occurring within the two reference cycles in the period of coverage. Both of these tests are weak. Furthermore, according to Stigler-Kindahl, buyer price changes are expected to lag seller price changes and price changes are expected to lag behind changes in industrial production; hence, both tests are likely to be biased. In particular, the bias will be toward accepting the dissimilarity of the two price indexes and towards accepting the administered-price thesis.

We can suggest alternative time domain tests of the hypotheses. First, the relationship between the *NB* and *BLS* indexes might be analyzed using the following regression:

$$\Delta NB_{ij} = \beta_{ij}\Delta BLS_{ij} \tag{1}$$

$$i = 1, n;\ j = 1, m$$

where i denotes the industry and j the time lag in months. The regression coefficient would be a measure of the average amplitude difference between the two series. Appropriate tests would be whether $\beta_{ij}>0$ and $\beta_{ij}>1$.

Second, to provide some insight into the administered-price thesis, a more powerful alternative to a simple examination of direction and magnitude of price changes within reference cycles would be the following relation between changes in industrial prices (Δp) and changes in the index of industrial production (ΔIP)

$$\Delta p_{kij} = \alpha_{kij} \Delta IP_{ij} \tag{2}$$

where k is the NB or BLS index, i the industry, and j the time lag. We would test whether $\alpha_{kij}>0$ and $\alpha NB_{ij}=\alpha BLS_{ij}$. Such a test potentially would establish whether the contour of price changes in the ith industry over the j-th time interval is correlated positively with the industrial production index IP and whether the amplitude differences in price behavior are significantly different between the NB and BLS indexes. However, while both time domain tests (1) and (2) potentially offer more powerful insights into the controversy, they suffer the same inherent problems of the weaker tests already undertaken by Stigler and Kindahl and Means. Unless the lags are appropriately specified, the tests will be biased, and there is no a priori basis for selecting one time lag over another.

In this paper, the important hypotheses in the debate are examined in the frequency domain, using spectral and cross-spectral techniques.[1] The use of a frequency domain approach to both the hypothesis of dissimilarity of the NB and BLS price indexes and the administered-price thesis is justified on the grounds that 1) the two issues essentially involve the relative frequency characteristics of different time-series and therefore the relevant hypotheses are conveniently formulated and tested in the frequency domain; 2) the frequency domain statistics to be used are not dependent upon a specification of the time lag (although some statistics, such as the phase, would require such a specification) and therefore avoid the time domain bias already discussed; and 3) spectral methods provide a convenient and efficient method for separating the variance of a time-series into cycles of different lengths and thus permit a comparison of variances over short, intermediate, and long-run periods.

I. *BLS-NB* Price Comparison

The *BLS* industrial price indexes are constructed from seller price lists, while the *NB* indexes are based on buyer prices. Stigler and Kindahl assert that the *BLS* procedure is deficient in several respects. The *BLS* indexes fail to capture price movements which result from discounts, changes in the terms of trade, and special concessions.[2] In addition, the *BLS* indexes are based upon a relatively small number of price reports (an average of one to three), while the number of reporters is a major determinant of the number of reported price changes.[3] The *BLS* procedure suggests a unique market price in which the buyer may shift from one supplier to another in response to better terms. The seller's price is for a precisely defined commodity, regardless of whether or not any is sold, while the buyer's prices reflect a wider range of commodities purchased continuously over time. These differences, among others, lead Stigler and Kindahl to conclude that "the seller's price quotations . . . will not display the multiplicity of prices and the frequency of revision that the transactions prices actually display" (p. 39).

To support their claim, Stigler and Kindahl examined 64 *BLS* and *NB* price indexes over the ten-year period from 1957 to 1966. The indexes were compared with respect to trend, cyclical fluctuations, and short-run movements. They find that slightly over half of the *BLS* indexes had steeper trends than the corresponding *NB* indexes, while the remainder were split between equal trends and steeper trends in the *NB* indexes, pp. 56–59. Comparing price changes during the reference cycle contractions (July 1957–Apr. 1958 and Jan 1960–Jan. 1961), they discover that "There are two *NB* price movements in the expected (downward) direction for each perverse change; in the *BLS* indexes the expected and perverse movements were virtually equal" (p. 61). When compared during two reference cycle expansions (Apr. 1958–June 1959 and Jan. 1961–Mar. 1962), "The *BLS* and *NB* price indexes . . . are essentially identical in their behavior" (p. 63). Finally, with regard to short-run movements, Stigler and Kindahl report that ". . . the *BLS* indexes usually change less frequently than the *NB* indexes. . . . But the movements of the *BLS* indexes are large and jerky" (p. 66). Correlating the first differences in the logarithms of the indexes, they find ". . . no close agreement in the monthly movements of the two indexes . . . the mean correlation coefficient is only .32 . . ." (p. 67). The mean correlations increase to .45 for quarterly changes, .54 for semiannual changes, and .59 for annual changes Furthermore, Stigler and Kindahl conclude that ". . . the quoted prices lag behind the changes in transactions prices by an unknown but appreciable time interval. The *NB* and *BLS* indexes are not very closely related in timing . . ." (p. 70).

---

[1] See Clive Granger and Michio Hatanaka or G. S. Fishman for a detailed discussion of spectral methods. For a more heuristic description of the technique, see Scully.

[2] Stigler and Kindahl also note that buyers were reluctant to disclose purchase prices for which an ". . . extraordinary favorable deal had been consummated" (p. 27).

[3] In contrast, the *NB* indexes used a total of 1,300 price reporters for 70 commodities, or an average of 17. Stigler and Kindahl add: "This heavier coverage reflects our distrust of the belief that there is only one price in a market at a given time" (p. 5).

The Stigler-Kindahl statistical comparisons of the *BLS* and *NB* price indexes suggest widespread differences in the behavior and character of these price series. However, neither Stigler and Kindahl nor Means have sought to test directly the hypothesis that the two series are obtained from essentially different stochastic processes. We propose to perform such a test using spectral techniques. Spectral density functions are decompositions of variance into frequency bands. The sum of the spectral density function is in fact the total variance in the time-series. We employ spectral methods because we are interested in the lag-adjusted behavior of these price indexes in several frequency bands, i.e., low, moderate, and high frequencies. In the spectral comparisons of the two indexes that follow, the spectral statistics were obtained using a Tukey-Hannan window with a maximal lag of 30 months and the sample data provided in the Appendix of the Stigler-Kindahl book. In the first test of similarity, spectral density functions were estimated for each of the 64 *BLS* and *NB* commodity indexes and then the power at each frequency of each *BLS* index was divided by the corresponding power of each *NB* index. Let $Q_i(w)$ represent this ratio of power at frequency w for commodity i and let $P_i(w)$ represent the ratio of the "true" power densities at frequency w for commodity i. The following $(1-\alpha)$ confidence interval holds:

$$P\left(F_{1-\alpha/2} \leq \frac{Q_i(w)}{P_i(w)} \leq F_{\alpha/2}\right) = 1 - \alpha$$

where $F_{\alpha/2}$ and $F_{1-\alpha/2}$ are the values from the F-distribution for α level of significance and (8, 8) degrees of freedom.[4] The null hypothesis to be tested is $P_i(w)=1$; that is, there is no significant difference between the spectra of the *BLS* and *NB* indexes at each frequency or that the two indexes simply reflect the same stochastic processes. Assuming the null hypothesis to be true, we should expect

$$P(F_{1-\alpha/2} \leq Q_i(w) \leq F_{\alpha/2}) = 1 - \alpha$$

However, the $(1-\alpha)$ confidence interval is somewhat wider with respect to all frequencies.[5] In particular, if we set the error rate at $.05/(m+1)$ where m is the number of lags (that is, a 5 percent chance of error at each frequency), the joint probability of committing any error over all $(m+1)$ frequencies will be no greater than .05.[6] For

---

[4] The number of degrees of freedom is given by $2n/m$ where n is the number of sample observations (120) and m the maximal lag (30).

[5] See Thomas Naylor, Kenneth Wertz, and Thomas Wonnacott for a discussion of this test. We thank Anthony Lawrence for calling our attention to this.

[6] The joint probability of an error over $(m+1)$ outcomes will not exceed the sum of the probabilities of

[a] Market dominated, according to Means, p. 306.

[b] Nonconforming to the business cycle, according to Means, p. 305.

$\alpha = .05$ and $m = 30$, the area in each tail of the F-distribution becomes .025/31, or .0008. Thus, the simultaneous confidence interval becomes

$$P(F_{.9992} \leq Q_i(w) \leq F_{.0008}) \leq .95$$

Of the total of 64 commodity indexes available for analysis, 46 had $Q_i(w)$ ratios that consistently fell within the 95 percent confidence bands. We conclude that the variance patterns of these 46 commodities are not significantly different whether measured by the *BLS* method or the *NB* method. This holds true for both long-run and short-run cyclical movements. Table 1 lists the commodity indexes that on this basis are judged not significantly different along with the remaining 18 commodity indexes where the $Q_i(w)$ ratios exceed the 95 percent confidence bands. Commodity groupings which exhibit the greatest similarity in the two indexes are Metals and Products, Paper Products, and Nonmetallic Mineral Products. The greatest differences in the spectra between the *BLS* and *ND* series are among Fuel Products, Rubber Products, and Chemical Products. Among the latter 18 commodities, it is of interest to note that 12 commodities or two-thirds showed the variance of the *BLS* index to be substantially greater than that of the *NB* index. Thus, only in 6 out of 64 cases was the variance of the *NB* index greater than that of the *BLS* index. Furthermore, this greater variance was not restricted to any particular frequency range but was verified in both high and low frequencies.

The coherence between the *BLS* and *NB* indexes shows a pattern similar to the correlations reported by Stigler and Kindahl. The coherences generally were larger in the lower than in the higher frequencies. As expected, the coherences were significantly greater for those commodities where the spectra were similar. Among this group, average coherences across all frequencies were in excess of .5. The average coherences among the remaining commodities generally were below .5.

In spite of the numerous similarities among the *BLS* and *NB* price indexes, it is important to consider whether the similarities tend to occur among commodities where prices are relatively constant or among commodities where prices are highly flexible. Accordingly, indexes of relative price variance were constructed for each of the 64 commodities by dividing the spectral density functions of each commodity by the spectral density functions of the aggregate industrial

---

each outcome. But the sum of $(m+1)$ probabilities, all with the same $.05/(m+1)$ probability, is simply .05. See Naylor et al.

price index. Four such indexes were obtained for each commodity, one for total variance (encompassing all frequencies), one for the variance attributed to the low frequencies (cycles having a period greater than 12 months), one for the variance attributed to the intermediate frequencies (cycles with a period between 3 and 12 months), and one for the variance attributed to the high frequencies (cycles with a period less than 3 months). The commodity indexes were ranked from highest to lowest on the basis of the relative variance. The rankings obtained on the basis of this procedure for the *BLS* price indexes were compared with those obtained for the *NB* price indexes.

The rank correlations between the variance rankings of the *BLS* and *NB* indexes are presented in Table 2. The rank correlations are all highly significant, although it is to be noted that the correlations decrease with the higher frequencies. The total frequency rankings were almost identical to the low frequency rankings, reflecting the common phenomenon among economic time-series that the bulk of the variance is attributable to the longer cycles.

TABLE 2—RANK CORRELATIONS BETWEEN THE VARIANCE RANKINGS OF THE *BLS* AND AND *NB* PRICE INDEX[a]

Rank Correlation		t-statistics
Total Frequencies	.754	8.962
Low Frequencies	.763	9.216
Intermediate Frequencies	.673	7.105
High Frequencies	.631	6.349

[a] The actual variance rankings for the 64 commodities over the various frequency intervals are available from the authors upon request.

We have also examined the variance ranking of each commodity index. Considering first the low frequencies of the top 20 ranked indexes (that is, the frequencies accounting for the bulk of the variance of the price indexes exhibiting the greatest variance), it is noted that nearly all of the commodities are in the group where the *NB* and *BLS* spectra are similar and that, with few exceptions, the top 20 indexes are the same commodities whether measured by the *BLS* or *NB* method. The notable exceptions include Insulated Copper Wire (C-16), which is ranked in the top ten by both measures but nevertheless had dissimilar spectra; Cardiac Glycosides (C-56), which ranks first using the *BLS*-method but 28th with the *NB* method; and Passenger Tires (C-24), which ranks 16th among the *BLS* indexes and 43rd among the *NB* indexes. All exceptions involved commodity indexes with dissimilar power spectra.

The same pattern holds for the high frequencies of the top 20 ranked indexes, though with less consistency. In fact, the same commodities generally appear among the top 20 in both the low and high frequencies. Again, the exceptions to the pattern develop among those commodities with dissimilar power spectrums.

The pattern is reversed among the 20 commodities with the smallest variances. In both the low and high frequencies, nearly half of these indexes have dissimilar power spectra. Furthermore, about half of the lowest 20 ranked *BLS* indexes are not the same commodities that appear among the lowest 20 ranked *NB* indexes. The most notable example here is Plywood (C-63), which is ranked seventh among the *BLS* indexes in the high frequencies, but sixtieth among the *NB* indexes.

These results suggest that there is considerable agreement and similarity between the *BLS* and *NB* methods of calculating price indexes when they are being used to measure price changes that are relatively large. The major differences between the *BLS* and *NB* indexes occur among those commodities where there is relatively little price variability.

II. Price Flexibility

According to Means, the "... administered-price thesis held that in business recessions administered-prices showed a tendency not to fall as much as market prices while the recession fall in demand worked itself out. ... Similarly, ... they tended not to rise as much in recovery ..." (p. 292). Thus, administered prices are held to be relatively inflexible over the course of the business cycle and perhaps, may move countercyclically. Stigler and Kindahl, however, interpret the thesis strictly in terms of the conformity of price movements to that of the general business cycle: "The main thrust of the doctrine of administered prices is that contractions in business lead to no systematic reduction of industrial prices, and much more equivocally, expansions in business may only tardily lead to price increases" (p. 7).

It is worth emphasizing that the administered-price thesis does not imply that industrial prices are inflexible with regard to factors other than transitive shifts in aggregate demand. That is to say, structural shifts in demand among industries or changes in cost functions in specific industries produce price changes generally unrelated to the business cycle and, as such, are not a matter of concern to the administered-price thesis. Changes in aggregate demand, on the other hand, are transitory phenomena in which different industries may respond variously through an inventory policy or price policy. Administered-price industries would tend to respond by varying output or inventories; other industries by altering prices.[7]

After examining the *NB* price data, Means disputes the Stigler and Kindahl conclusion that industrial prices tend to move in response to the business cycle. Means regards 13 of the 64 commodity indexes as market dominated. He shows that 30 of the remaining 51 failed to move in conformity with changes in business activity in three or four times out of a possible four opportunities (i.e., the contractions and recoveries of 1958–59 and 1961–62, (pp. 304–04)). However, of these 30 only 10 were completely perverse in all four opportunities. Moreover, Means argues that the prices of the 13 market-dominated commodities tend to behave "quite differently" relative to the administration-dominated prices. ". . . thus confirming the administered-price thesis" (pp. 303–04).

It is of interest to note that of the 13 commodities Means designated as market dominated, 10 are in the group of Table 1 where the *BLS* and *NB* spectra are not significantly different. Furthermore, of the 10 commodities that were completely perverse with respect to the business cycle, 6 were among the 46 commodities with similar spectra and 4 were in the group with dissimilar spectrums.

The average rank of the two groups is significantly different as well. The market dominated commodities tend to fall among the top 20 variances, with an average ranking of 19–20 in both the high and low frequencies. The nonconforming commodities, on the other hand, tend to have much lower variances, with an overall average ranking between 39 and 43. Thus, the results tend to confirm Means' version of the administered-price thesis which emphasizes relative price inflexibility.

The Stigler-Kindahl version of the administered-price thesis emphasizes the conformity of price movements to the business cycle. To test the Stigler-Kindahl version, we estimated cross-spectral density functions of the *BLS* and *NB* price indexes using the index of industrial production as the base series. The industrial production index is widely regarded as the single best indicator of the business cycle. The main statistic of interest here is the coherence square, which is a measure of the degree of association between the two series calculated at each frequency. The coherence relationship between each commodity price index and the industrial production index is described as either very low, low, moderate, or high depending on the magnitude and consistency of the coherences over all 30 frequencies (see the footnote to Table 3 for definitions). The sign of the cospectrum is reported to indicate whether a significant coherence relationship is inverse (negative) or direct (positive). Low and very low coherences imply that the two series are not sufficiently related to consider the sign and are designated as not applicable (*n.a.*). The last two columns of Table 3 indicate whether a significant coherence relationship is in-phase (*IN*) or out-of-phase (*OUT*). Two series are considered in-phase if the quadrature spectrum is consistently less than the cospectrum.

---

[7] We have investigated the behavior of output amplitudes in specific administered-price industries. These results are not presented here for two important reasons. First, the *BLS-NB* industrial price classifications differ substantially from the Federal Reserve Board industrial production classification, raising doubts about comparability. Second, where price adjustments are avoided in favor of output adjustments, inventories ought to be the primary focus of attention. Inventory data by volume are even more scarce than output data. Furthermore, without knowledge of the costs of holding and adjusting inventory stocks, interindustry comparisons of inventory adjustments over the business cycle would be inappropriate.

A price series which is completely perverse with respect to the index of industrial production would be one in which the coherence is moderate or high, the sign of the cospectrum is negative, and the two series are in-phase. A price series which consistently conforms to the cyclical pattern of industrial production differs from that of the

TABLE 3—COHERENCE, SIGN OF COSPECTRUM, AND PHASE OF *NB* AND *BLS* PRICE INDEXES COMPARED TO THE INDUSTRIAL PRODUCTION INDEXES FOR CASES WHERE COHERENCE WAS MODERATE OR HIGH[a]

C-62	*H*	*L*	–	*n.a.*	*OUT*	*n.a.*
C-64[f]	*VL*	*H*	*n.a.*	+	*n.a.*	*IN*

[a] Only those cases where the *NB* or *BLS* price indexes were moderately or highly coherent with the Industrial Production Index are reported. In all of the unreported cases the coherences were low or very low.

[b] The coherence descriptions are defined as follows: Very Low (*VL*): most coherences are below .25; Low (*L*): most coherences below .4 with a few above .4; Moderate (*M*): most coherences between .3 and .6; High (*H*): some coherences above .8, most above .5. (See Clive Granger and Oskar Morgenstern, p. 20.)

[c] The signs indicate that the coherence is negative or positive, while *n.a.* means that the sign is not relevant because the coherence is too low.

[d] The coherences are labelled in-phase or out-of-phase depending on the magnitude of the quadrature spectrum relative to the cospectrum. Again, *n.a.* indicates that the phase relationship is not relevant because of the lack of coherence.

[e] See fn. b, Table 1.

[f] See fn. a, Table 1.

above only with respect to the sign of the cospectrum. When the coherence is low, prices may be positively or negatively related to a given upswing or downswing in industrial production (such as the two cycles considered by Means and Stigler and Kindahl), but the overall coherence may be too low to reveal a consistent and significant cyclical relationship. This may be considered a shortcoming of an analysis which considers the cross-spectral results across all frequency bands rather than a selected few. However, two cycles hardly provide sufficient degrees of freedom on which to base statistical conclusions. Furthermore, the spectral density function of industrial production reveals a rather smooth downward sloping curve typical of economic time-series, where the variance attributed to cycles with a period of around two years is not sufficiently large to warrant a concentration of emphasis.[8] In fact, the lack of important peaks in the spectral density of industrial production suggests the necessity for emphasizing the cross-spectral results over all frequency bands (as in Table 3) rather than concentrating on individual frequency bands.

The most notable feature of the results in Table 3 is the large proportion of price series that have no significant coherence with the index of industrial production. Measured by the *BLS* method, 52 out of 64 indexes have low or very low coherences, while 41 of the *NB* indexes are so described. Thus, the bulk of these so-called administered-price series has no apparent cyclical relationship with industrial production. It is interesting to note, moreover, that the *BLS* indexes present this picture more definitively than the *NB* indexes. The lack of coherence between prices and output in general is consistent with Means' view of the administered-price thesis. However, the results do suggest the danger of basing such a conclusion on the lack of conformity of prices with just two swings in the business cycle.

Of the indexes which are significantly coherent with industrial production, there are some rather interesting differences in the *NB* and *BLS* indexes. These differences may partially account for the opposite conclusions reached by Means and by Stigler-Kindahl. The 12 *BLS* indexes that exhibited moderate or high coherences include 9 with positive cospectra and only 3 with negative cospectra. Thus, of those prices coherent with industrial production, the bulk move in conformity with output rather than countercyclically. However, of the 23 *NB* indexes with significant coherences, only 12 had positive cospectra. It is somewhat ironic that the *BLS* indexes support the Stigler-Kindahl position while their own price indexes provide no useful information one way or the other on this issue.[9]

Another feature of these results is that of the 9 *BLS* and 12 *NB* indexes that show conformity with the index of industrial production, 7 *BLS* and 8 *NB* indexes are among the group of 13 commodities that were labeled by Means as market dominated. The remainder had insignificant coherences. On the other hand, of the 3 *BLS* and 12 *NB* indexes with negative cospectra, none of the *BLS* and only 3 of the *NB* indexes were in the group of 10 commodities Means cites as completely perverse with respect to the business cycle. Otherwise, these commodities showed insignificant coherences.

Finally, the *BLS* and *NB* indexes generated about the same pattern of coherences with industrial production. Thirty-seven commodities had low or very low coherences with both indexes, while 9 commodities had moderage or high coherences with both indexes. It was expected that some differences in coherences would arise in cases where the power spectrum was significantly different between the *BLS* and *NB* indexes (as described in Table 1). Strangely enough, however, only 5 of the 18 commodities with different coherences had significantly different power spectra, which is no different than one would expect from a random drawing.

---

[8] See Scully for a discussion of the spectral shape of the industrial production index.

[9] Note, however, that 3 of the 13 *NB* indexes with negative cospectra are out-of-phase with output and may therefore appear in the time domain to move positively with output.

III. Conclusion

On the basis of the statistical results obtained by employing spectral and cross-spectral techniques to the *NB* and *BLS* industrial price series, we conclude that 1) for the most part, these two series reflect similar stochastic processes, and 2) administered prices do appear to be a feature of the *U.S.* economy. However, these conclusions require some qualification in view of the lack of universal evidence. Our analysis shows that nearly three-fourths of the Stigler-Kindahl price indexes have spectra similar to those of the *BLS* price series. Where the two indexes do differ, the commodity prices involved generally show relatively little variance anyway. Researchers who employ industrial price indexes can be indifferent between the *NB* and *BLS* series except for the cases we have noted.[10] It would not seem very profitable to follow the Stigler and Kindahl recommendation and proceed to gather information on buyers' prices universally. The Stigler-Kindahl conclusion of a general difference in the behavior of their price series in comparison to the *BLS* series would not appear warranted.

With regard to whether administered prices are a feature of the *U.S.* economy, we find little evidence to support the Stigler-Kindahl contention of conformity between the price indexes of these industries and the business cycle. Among the *BLS* series, 80 percent showed no conformity with the business cycle. Among the *NB* prices, the Stigler-Kindahl version of the administered-price thesis did somewhat better, but still 41 of 64 series had low or very low coherence with the industrial price index. Furthermore, the proportion showing nonconformity with the business cycle rises to three-quarters when the market-dominated commodities are removed from the list. Where there was conformity in the *NB* price series with the business cycle, nearly half the cases show a perverse correlation. Actually, it is the *BLS* indexes which more strongly support the Stigler-Kindahl argument. Here, three-quarters of the significantly coherent cases indicated cyclical conformity of price and output. But, it is important to note that 6 of 9 positive cospectra of the *BLS* series and 7 of the 12 positive cospectra of the *NB* series actually were market-dominated commodities. Hence, evidence of cyclical conformity of prices and output in administered-price industries appears very thin indeed.

---

[10] George Hay used the *NB* price indexes to reestimate certain equations in his model. The goodness of fit statistic for the price equation improved only in the Paper industry.

Buyer's Prices, Seller's Prices, and Price Flexibility: Reply

By GEORGE J. STIGLER*

The application by Douglas Bohi and Gerald Scully of spectral analysis to the price data presented in the book written by James Kindahl and myself is unsuccessful whether judged by economic or statistical criteria. The main deficiencies are five:

1. The spectral analysis is applied to the price indexes corrected for trend. This procedure preserves the high serial correlation in the price series even for long lags. The analysis should have been applied to the first differences in the price indexes or to the first differences in their logarithms.[1]

2. Spectral analysis is based upon the assumption that one is dealing with a stationary, Gaussian time-series. The reported high serial correlations are a denial of the stationarity of the price series. The numerous Board of Labor Statistics (*BLS*) price series with few but large movements do not fit the Gaussian assumption and their behavior cannot be characterized by spectral densities.

3. If two time-series have the same spectral density functions, this does *not* assert that the two series resemble each other in the least: two random price series, for example, would have the same spectral densities, but be uncorrelated. Bohi and Scully make no detailed analysis of the coherence (correlation) of the two sets of price series.

4. The *power* of the tests employed to determine whether the *BLS* and National Bureau price series have the same spectral densities is extremely low. The method used by Bohi and Scully to combine the 31 spectra further reduces the power of the tests. It is therefore remarkable that 18 of 64 pairs of price series are determined to be different.

5. The confidence intervals used to judge the significance of the differences in the spectral densities are F-tests, for whose validity it is necessary to assume that the two price series are *independent*. The test is then used to conclude that usually they are not independent.

ERRATA

Please note corrections and additions to the October 1974 *Directory of Members*

I. Due to editorial errors, the following corrections are noted

Correct Name

Bornhofen, John O. (Listed as Barnhofen, John O.)
Hoffmann, Charles. (Listed as Hoffman, Charles)
López-Mangual, Juan. (Listed as Mangual, Juan López)
Mattart, Fernand. (Listed as Fernand, Mattart)
Sparks, Zoe Ann. (Listed as Sparks, Jr., Jared)
Talmers, William N. (Listed as Talmere, William N.)
Van Roy, Edward. (Listed as Van, Al, Edward)
Vander Weide, James H. (Listed as Weide, James Vander)

Correct Previous and Current Position

Feinn, Barbara A. Cur. Pos. Chief Economist, State of South Carolina.

Harbeson, Robert W. Prev. Pos. Assoc. Prof. 1947–54, Prof., 1954–65, McKinley Prof. of Econs., U. of Ill., 1965–71.

Kaser, Michael. Cur. Pos. Professorial Fellow; Reader in Economics, St. Antony's College, Oxford U.

Correct Degree

Gruen, Edward D. Educ. Ph.D.-elect, Duke U., 1949 (incorrectly given as completed).

Lipsky, John P. Educ. Ph.D. (expected), Stanford U., 1974 (incorrectly given as completed).

Correct Address

Spiro, Michael H. Address Senior Economist, U.S. Dept. of Commerce, Office of the Secretary, Washington, DC 20230. (Mr. Spiro was incorrectly listed as Chair, Dept. of Economics, U. of Pittsburgh.)

Classification by Academic Affiliation

We appreciate the time members took to write us about the numerous errors in the Geographical List of Members. Space constraints are such that we cannot print the corrections. It is evident that this section will require special handling in the next edition of the *Directory,* which should be published in the next five years.

Names of Administrative Officers of Departments of Economics have been corrected on the mailing list maintained by the Association.

The Association does not keep corrections and additions on file for future editions of the *Directory.* Please do not send questionnaires to the Association office or to the data service company. Members in good standing at the time the next *Directory* is published will be asked to correct their 1974 listing or submit a new questionnaire.

NOTES

Announcement of Changes in Editorial Policy

The May 1975 issue of the *Review* (*Papers and Proceedings*) contains a financial report by the Secretary-Treasurer for the year 1974, and a projection of operations for 1975. Due to sharp increases in printing and mailing costs, in salaries and office expenses, and to the increased scope of the Association's activities, 1974 expenses outpaced revenues by more than $125,000. This situation will worsen in 1975. While a small fraction of these expenses are accruals to reserves (such as the cost of producing the membership *Directory*), the deficit represents in large part a cash loss which must be met in the short run by borrowing or liquidation of securities and in the long run by economies of operation and increased revenues. Accordingly the following methods of reducing cost or raising revenue have been recommended to the Executive Committee, and accepted at its meeting on March 14, 1975.

a) The discontinuance of free reprints/offprints to authors of material appearing in the *American Economic Review* and *Journal of Economic Literature*. Reprints /offprints will continue to be sold at prices which cover the relevant costs. This change will begin with the December 1975 issues.

b) A differential submission fee for authors who are not members of the American Economic Association. Beginning July 1, 1975, the submission fee for manuscripts submitted to the *American Economic Review* will be fifteen dollars ($15) for members and thirty dollars ($30) for nonmembers.

c) A postage surcharge for mailing of material outside the United States. This surcharge will equal the difference between mailing costs inside and outside the United States. It will be added to new subscription and membership bills January 1, 1976.

d) A page charge for articles, shorter papers, notes, comments, and replies published in the *American Economic Review* and in the *Journal of Economic Literature*. The page charge is payable by the institution or granting agency supporting the research. Payment of this charge is not a prerequisite for publication, nor are authors expected to pay these charges themselves. The charge will be twenty-five dollars ($25) per printed page, and will go into effect with manuscripts accepted after July 1, 1975.

Nominations for AEA Officers

The Electoral College on March 14 chose Lawrence R. Klein as nominee for President-Elect of the American Economic Association in the balloting to be held in the autumn of 1975. Other nominees (chosen by the nominating committee) are: for Vice-President (two to be elected), Barbara R. Bergmann, Harry G. Johnson, Douglass C. North, and Albert E. Rees; for member of the Executive Committee (two to be elected), Robert W. Fogel, Bert G. Hickman, Edmund S. Phelps, and Alice M. Rivlin.

Under a change in the bylaws as described in the *Papers and Proceedings* of this *Review*, May 1971, page 472, additional candidates may be nominated by petition, delivered to the Secretary by August 1, including signatures and addresses of not less than 6 percent of the membership of the Association for the office of President-Elect and not less than 4 percent for each of the other offices. For the purpose of circulating petitions, address labels will be made available by the Secretary at cost.

1976 Nominating Committee of the AEA

In accordance with Section IV, paragraph 2, of the bylaws of the American Economic Association as amended in 1972, President-Elect Franco Modigliani has appointed a Nominating Committee for 1976 consisting of Kenneth Arrow, Chairman; William James Adams; Duran Bell; Marianne Ferber; Jack Hirschleifer; Leonard Rapping; and Vincent Tarascio. Attention of members is called to the part of the bylaw reading, "In addition to appointees chosen by the President-elect, the Committee shall include any other member of the Association nominated by petition including signatures and addresses of not less than 2 percent of the members of the Association, delivered to the Secretary before December 1. No member of the Association may validly petition for more than one nominee for the Committee. The names of the Committee shall be announced to the membership immediately following its appointment and the membership invited to suggest nominees for the various offices to the Committee."

Nicolaus and Associates have been appointed the official travel coordinator for the Dallas meetings of the Allied Social Science Associations. Group air fares may be arranged from your city and for groups as small as fifteen. These fares usually run about 25 percent below regular coach fare. Some examples using current fares subject to change are:

	Coach	Group
New York-Dallas-New York	$236.73	$159.73
Des Moines-Dallas-Des Moines	124.73	99.73
San Francisco-Dallas-San Francisco	252.73	202.73

Flights will be arranged for other cities if enough individuals show interest. Air reservation forms and general information on flights and costs will be mailed to you in October with the preregistration material. In the meantime if you have any questions on group flights, please call Nicolaus and Associates collect at 817-461-1622, or write them at 1201 N. Watson Road, Suite 179, Arlington, Texas 76011.

The German Marshall Fund of the United States, an American private foundation, announces that *German Marshall Fund Common Problems Fellowships* will be available in 1976 to outstanding U.S. scholars whose work is designed to contribute "to the better understanding and resolution of significant contemporary or emerging common problems of industrial societies," particularly in their comparative, international, social, political and economic aspects. Write for information and application form (deadline Oct. 31, 1975) to the German Marshall Fund, 11 Dupont Circle, N.W., Washington, D.C. 20036.

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The deadlines for applications to be received in the office of the American Economic Association are: for meetings scheduled between June and September, February 15; for meetings scheduled between October and January, June 15; for meetings scheduled between February and May, October 15. Application forms may be obtained from Rendigs Fels, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

The eighty-eighth annual meeting of the American Economic Association will be held in Dallas, Texas, December 28–30, 1975. The Employment Registry and Center will open December 27. The meeting was originally scheduled for October, but has been changed in the interest of attracting greater attendance. The preliminary program of the meeting will appear in the September 1975 issue of this *Review*.

Besides its normal run, *Social Science Quarterly* periodically organizes and publishes special issues dealing with specific topics that are timely and will be of interest to its multidisciplinary audience. Planned for 1976 is a special issue focussing on "Society and Scarcity." It will be devoted to theoretical and empirical inquiries into various aspects of this topic: including human adaptations (or lack of adaptations) to scarcity, equity, and the distribution of income; power and the distribution of income; the distribution of income and social conflict; the international distribution of income and international relations; scarcity and social values (particularly the impact of scarcity on environmental protection and conservation); food and the future; and the energy crisis. Short to medium length manuscripts (12–29 pages) dealing with any aspect of this topic are invited, and should be submitted for consideration before November 1, 1975, to the Editor, *Social Science Quarterly*, University of Texas, Austin, Texas, 78712.

A conference on The Ukraine Within the USSR After World War II: An Economic Balance Sheet will be held at the Harvard Ukrainian Research Institute, Harvard University, 1581–1583 Massachusetts Avenue, Cambridge, Massachusetts, on Friday and Saturday, September 26 and 27, 1975. The conference will consist of three sessions at which eleven papers will be presented and discussed. For further information contact Professor I. S. Koropeckyj, Department of Economics, Temple University, Philadelphia, PA 19122.

The next volume (XIV) of the *Annals of the Ukrainian Academy of Arts and Sciences in the U.S.A.* will be devoted to economic problems. Articles on the current situation of Ukrainian economy, history of Ukrainian economy, the history of economic thought in the Ukraine, and reviews of relevant works are solicited. The deadline for submitting of articles and reviews is the end of 1975. Publication of the issue is planned for the middle of 1976. Professor I. S. Koropeckyj, Department of Economics, Temple University, Philadelphia, PA 19122.

The International Savings Banks Institute, Geneva, Switzerland, has organized an international prize competition on the subject of:

> Indexation of monetary assets and (credit) obligations—pros and cons, taking into account probable effects on banking and the economy; practical possibilities and consequences.

First prize is 15,000 Swiss francs. Second prize is 5,000 Swiss francs. Inquiries and correspondence should be addressed to: International Savings Banks Institute, 1-3 Rue Albert-Gos, 1206 Geneva, Switzerland.

The Urban and Regional Information Systems Association (URISA) is holding its 13th annual conference at the Washington Plaza Hotel in Seattle, Washington, August 24–28, 1975. The theme will be The Role of Information Systems Technology in Community Management.

Urban Economics, a special summer program, will be held at Massachusetts Institute of Technology, August 11–22, 1975, featuring classroom work and distinguished lecturers discussing the most recent theoretical and empirical economic findings in the area of urban economics ranging from housing and transportation to the provisions organization and pricing of government services, etc. For further information, please write to: Director of the Summer Session, Room E19-356, M.I.T.; Cambridge, Massachusetts 02139.

The second annual meeting of the European Finance Association will be held from September 24–26 at the London Business School. For information, write to: Professor Richard Brealey, London Business School, Sussex Place, Regent's Park, London, NW1.

Call for Papers

The purpose of this special issue of *Management Science* on the Leisure Industry is to present a variety of applications of OR/MS techniques to the activities of the leisure-time industry, and to attract additional practitioners into this area of applications. The issue will contain both invited and contributed papers. Papers should deal with any aspect of the leisure-time industry: tourism, travel, recreation, gambling, arts, and lodging. Optimization studies (e.g. optimal utilization of an amusement park, optimal facility mix for private or public facilities such as country clubs, parks, wilderness areas, etc.) are preferred, although statistical analysis will also be considered. Validated applications are encouraged. The length of papers should not exceed 20 journal pages. Short notes will also be considered. All papers will be subject to the normal refereeing process. The issue is being coedited by Shaul P. Ladany, Haifa University, and V. Kerry Smith, State University of New York at Binghamton, Department of Economics, Binghamton, New York 13901. Send abstracts or descriptions of your topic. Completed manuscripts (4+4 copies) will be required by December. All correspondence should be sent to V. K. Smith.

The University of Missouri-Rolla, in cooperation with the Missouri Energy Council is sponsoring the second annual UMR/MEC Energy Conference to be held at the University of Missouri-Rolla, October 7–9, 1975. The program chairpersons for economics are Christopher Garbacz and Vaman Rao, Department of Economics, University of Missouri-Rolla, Missouri 65401.

The Rockefeller and Ford Foundations are continuing for a fifth year a program in support of population policy research in the social sciences. The program is designed to encourage research on the socioeconomic determinants and consequences of population behavior relevant to the process of population policy formulation and implementation. Proposals must be received by July 1, 1975. Awards will be announced by the end of December 1975. All inquiries and proposals should be sent directly to The Rockefeller-Ford Program for Population Policy Research, The Rockefeller Foundation, P.O. Box 4516, Grand Central Station, New York, New York 10017.

Deaths

Procter Thomson, professor of economics, Claremont Men's College, Jan. 26, 1975.

Retirements

Willard D. Arant, economist, Swift and Company, Nov. 1975.

George W. Zinke, department of economics, University of Colorado, Aug. 1973.

Visiting Foreign Scholars

B. Curtis Eaton, Queen's University: visiting scholar, department of economics, University of Colorado, 1974–75.

Richard Lipsey, Queen's University: visiting scholar, department of economics, University of Colorado, 1974–75.

Motoaki Moriya, Kansai University, Asaka, Japan: visiting scholar, department of economics, University of Colorado, Jan. 1975.

Promotions

Roy C. Anderson: associate professor, department of economics, California State University, Long Beach.

G. Knight Boyer: associate professor, department of economics, geography and management, U.S. Air Force Academy, July 1, 1974.

John S. Brush: associate professor, department of economics, geography and management, U.S. Air Force Academy, July 1, 1973.

James F. Crook: associate professor of economics and statistics, Winthrop College, Aug. 1974.

James J. Doyle: assistant professor, department of economics, John Carroll University.

Fred R. Glahe: professor, department of economics, University of Colorado, fall 1973.

Arthur Kraft: professor, department of economics, Ohio University, June 1975.

Mary Lou Larmore: associate professor, department of economics, California State University, Long Beach.

Perry W. Polk: assistant professor, department of economics, geography and management, U.S. Air Force Academy, July 1, 1974.

Robert F. Rooney: professor, department of economics, California State University, Long Beach.

Larry D. Singell: professor, department of economics, University of Colorado, June 1973.

Andrew Stern: associate professor, department of economics, California State University, Long Beach.

Robert L. Taylor: assistant professor, department of economics, geography and management, U.S. Air Force Academy, July 1, 1973.

Murray Yanowitch: professor, department of economics, Hofstra University, Dec. 16, 1974.

Administrative Appointments

Edward L. Claiborn: professor; head, department of economics, geography and management, U.S. Air Force Academy, Aug. 1, 1974.

Simeon J. Crowther: chairman, department of economics, California State University, Long Beach.

Herbert C. Morton, Bureau of Labor Statistics: director of public affairs, Resources for the Future, Feb. 1975.

Charles E. Staley: acting chairman, department of economics, State University of New York, Stony Brook, Feb. 4, 1975.

Appointments

James T. Bennett, George Washington University: associate professor of economics, George Mason University, Sept. 1975.

Claire Bombardier: research fellow, National Bureau of Economic Research, Jan. 6, 1975.

Yale N. Braunstein, Stanford University: research associate in economics, New York University, Sept. 1974.

E. J. Devine: associate director, Defense Manpower Commission, Nov. 1974.

Thomas P. Drinka: research associate, department of economics, Iowa State University, Nov. 1, 1974.

Margo Faier: economist, Banking Studies Division, Federal Reserve Bank of New York, Oct. 10, 1974.

Francis Lea Kaiser: research associate, department of economics, Iowa State University, Oct. 3, 1974.

Richard D. Karfunkle: chief economist; director, economics group, Lehman Brothers, Inc., Jan. 1975.

Avram Kisselgoff: senior research associate, National Bureau of Economic Research, Nov. 1, 1974.

John F. Kyle, Exxon Corporation: assistant professor of economics, New York University, Sept. 1974.

Ludwig Lachmann, University of Johannesburg, South Africa: visiting professor of economics, New York University, Feb. 3, 1975.

Richard A. Levins: research associate, department of economics, Iowa State University, Dec. 20, 1974.

Treena K. Levins: research associate, department of economics, Iowa State University, Dec. 20, 1974.

Ann R. Markusen: assistant professor, department of economics, University of Colorado, Spring 1974.

A. James Meigs, Argus Research Corporation: professor of monetary theory and banking practices, Claremont Men's College, Feb. 1975.

Warren E. Moskowitz, Exxon Corporation: assistant professor of economics, New York University, Sept. 1974.

Gordian Nworah: economist, Banking Studies Division, Federal Reserve Bank of New York, July 25, 1974.

Craig W. O'Riley: research associate, department of economics, Iowa State University, Nov. 16, 1974.

Joel Popkin: senior research associate, National Bureau of Economic Research, Nov. 1, 1974.

William Rutledge: economist, Banking Studies Division, Federal Reserve Bank of New York, Sept. 5, 1974.

Thomas A. Wolf, International Institute of Management, Berlin, Germany: assistant professor, department of economics, Ohio State University.

Edward N. Wolff, Yale University: assistant professor of economics, New York University, Sept. 1974; research associate, National Bureau of Economic Research, Nov. 1, 1974.

Leaves for Special Appointments

Elbert V. Bowden, State University of New York, College at Fredonia: team leader, United Nations regional economic planning team, Fiji Islands, 1975–76.

David E. R. Gay, University of Arkansas: visiting scholar, Institute on Soviet and East European Studies, University of Glasgow, May 1975.

Leslie E. Grayson, University of Virginia: Ford Foundation award, visiting professor, European Graduate Institute of Business Administration, 1974–75.

Karl D. Gregory, Oakland University: visiting faculty professor, State University of New York, Buffalo, Jan. 6, 1975.

Robert L. Harlow, College of the Holy Cross: international economist, Office of International Monetary Affairs, U.S. Treasury Department, Jan. 6, 1975.

Toussaint Hočevar, University of New Orleans: Fulbright-Hays senior researcher, University of Ljubljana, Slovenia, Feb.–June 1975.

Arthur Kraft, Ohio University: Sears-AACSB Federal Faculty Fellow, Office of Research and Statistics, Social Security Administration.

Dudley G. Luckett, Iowa State University: visiting professor, department of economics, University of Tulsa, Feb.-May 1975.

Alexander Melamid, New York University: visiting professor of economic geography, University of Sydney, Australia.

Resignations

David Calvin Gogerty, The Rand Corporation, Oct. 1974.

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:
A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3×5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

NOTICE TO ALL GRADUATE DEPARTMENTS

The December 1975 issue of the *Review* will carry the seventy-second list of doctoral dissertations in political economy in American universities and colleges. The list will specify doctoral degrees conferred during the academic year terminating June 1975. This announcement is an invitation to send us information for the preparation of the list. This announcement supersedes and replaces a letter which was sent annually from the managing editor's office.

The *Review* will publish in its December 1975 issue the names of those who will have been awarded the doctoral degree since June 1974 and the titles of their dissertations. Dissertation abstracts will no longer be published, as these are published elsewhere.

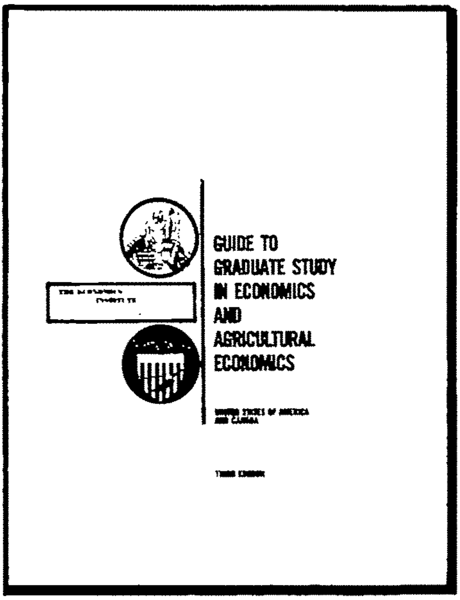
By June 30, please send us this information on 3×5 cards, conforming to the style shown below, one card for each individual. Please indicate by a classification number in the right-hand corner the field in which the thesis should be classified. The classification system is that used by the *Journal of Economic Literature* and printed in every issue.

JEL Classification No. ________
Name: LAST NAME IN CAPS: First Name, Initial
Institution Granting Degree: ________
Degree Conferred (Ph.D. or D.B.A.) ________ Year ________
Dissertation Title: ________

When degrees in economics are awarded under different names, such as Business Administration, Public Administration, or Industrial Relations, candidates in these fields whose training has been *primarily in economics* should be included.

All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

Announcing...



GUIDE TO GRADUATE STUDY IN ECONOMICS AND AGRICULTURAL ECONOMICS

Guide to Graduate Study in Economics and Agricultural Economics

in the United States of America and Canada

THIRD EDITION

Designed to provide students anticipating graduate study in economics and agricultural economics, and their advisors, with information on available graduate training programs.

Includes descriptions of 236 graduate programs, supplemented by comparative data and information for prospective students, domestic and foreign.

Published by the Economics Institute under the auspices of the American Economic Association, and the American Agricultural Economics Association.

Distributed by:
RICHARD D. IRWIN INC.,
1818 Ridge Road,
Homewood, Illinois 60430

PRICE: $7.50 per copy

DETENTE AND DOLLARS:

Doing Business with the Soviets

Marshall I. Goldman

This indispensable book by a leading expert in East-West trade, provides the American businessman with the perspective and information he needs to decide whether he too should enter the billion-dollar Soviet market and, if so, how he can do it successfully. Dr. Goldman draws important lessons from his detailed inside account of both costly failures (the great American grain disaster of 1972) and success stories (Armand Hammer and the Pullman Corporation) in doing business with the Soviet Union.
Due June $10.00

HOUSING AND THE MONEY MARKETS

Roger Starr

Here is the first systematic introduction to the money markets as they relate to housing. Now Administrator of New York City's Housing and Development Administration, Mr. Starr describes the various institutions that extend mortgages and shows how they finance housing construction. He explores the relationship between lending institutions and the various government agencies such as the FHA, GINNY MAE, and FANNY MAE that have been set up for channeling savings into mortgages. "Timely as well as valuable. . . . An excellent primer and a well reasoned policy text for specialists and government officials."—LOUIS WINNICK.
Just published $10.95

ANARCHY, STATE AND UTOPIA

Robert Nozick

In the most challenging defense of property rights and free enterprise in modern times, Professor Nozick poses, as *Forbes* puts it, "nothing less than a challenge to a central feature of the moral landscape: the state as everybody's mother and father."—*Forbes.* "No contemporary philosopher possesses a more imaginative mind, broader interests, or greater dialectic abilities."—*Harpers.* Published $12.95

WHO SHALL LIVE?

Health, Economics, and Social Choice

Victor R. Fuchs

"A short lucid, uncomplicated explanation of the economics of health care. . . . No book has demonstrated a better grasp of the *social* context of health and health care, of the idea that central social changes, rather than mere technical tinkering with the system is at issue. Most useful."
—*The New York Times Book Review.*
Just published $8.95

CRISIS IN KEYNESIAN ECONOMICS

Sir John Hicks

Black-White Income Differentials

Empirical Studies and Policy Implications

by STANLEY H. MASTERS

A Volume in the INSTITUTE FOR RESEARCH ON POVERTY MONOGRAPH Series

This book investigates why urban blacks have lower incomes than whites in similar occupational positions. Professor Masters presents statistical tests of three widely held hypotheses of urban black discrimination—1) southern migrants cause the low income of blacks in northern cities, 2) housing segregation causes significant problems for urban black males, 3) differences in productivity are more important than labor-market discrimination. The book presents data showing that the first two hypotheses are false and the validity of the third depends upon assumptions about the reliability of years of schooling or test-score performance as measures of productivity. The author concludes that much of the racial differential in earnings results from labor-market discrimination.

CONTENTS: Economic Theories of Discrimination. A Review of Empirical Studies of Discrimination Against Blacks. The Effect of Migration on Black Incomes. The Effect of Housing Segregation on Black-White Income Differentials. Estimating the Relative Importance of Labor-Market Discrimination Versus Differences in Productivity Between Blacks and Whites. Alternative Policy Perspectives. Policy Recommendations.

1975, 204 pp., $12.50/£6.00

Stochastic Optimization Models in Finance

edited by W. T. ZIEMBA and R. G. VICKSON

A Volume in the ECONOMIC THEORY AND MATHEMATICAL ECONOMICS Series

This book fills the need for a thorough account of the mathematical and economic theory relevant to stochastic optimization of models of financial problems that involve uncertainty. Almost every article presents a significant methodological advance of lasting interest for teaching and research in finance.

The book is divided into five parts: Mathematical Tools; Qualitative Economic Results; Static Portfolio Selection Models; Dynamic Models Reducible to Static Models; and Dynamic Models; each part opens with a detailed, cohesive introduction and includes both computational and review, and mind-expanding exercises, to test and widen understanding.

1975, 744 pp., $24.50/£11.75

Prices subject to change without notice.

Economic Policymaking in a Conflict Society

The Argentine Case

Argentina is a fascinating and baffling case to scholars of economic development. It has rich agricultural resources, a fully monetized economy, a domestic manufacturing sector that occupies a large share of the active labor force, a relatively high level of literacy, and other attributes that resemble a European nation more than a developing country. At the same time, Argentina has found it difficult to develop the institutions of a modern nation-state and to sustain a satisfactory rate of economic growth. This book is a new and vigorous attempt to explain the Argentinian paradoxes. $16.00t

Harvard University Press

79 Garden Street, Cambridge, Massachusetts 02138

ESSAYS ON JOHN MAYNARD KEYNES

Edited and compiled by MILO KEYNES

A new collection of essays revealing little-known facets of Keynes' life and interests and presenting new interpretations of his economic theories. Among the distinguished contributors are: Austin Robinson; Harry G. Johnson; Joan Robinson; John Kenneth Galbraith; and R. B. Braithwaite. The book includes a chronology, a bibliography and an index, and is illustrated with photographs. $16.50

INTERNATIONAL TRADE AND FINANCE

Frontiers for Research

PETER B. KENEN

This volume, based on a conference at the International Finance Section of Princeton, addresses itself to three questions: What have we learned from recent empirical research? What are the main gaps in present knowledge? How should we go about filling those gaps? Here you will find original articles by most of the major figures in the field including R. M. Stern, W. M. Corden, C. Diaz-Alejandro, B. Balassa, S. P. Magee, J. Helliwell, B. J. Cohen, L. R. Klein, and R. E. Caves. There is also a concluding *Overview* by Kindleberger, Chenery, Bhagwati, R. N. Cooper, W. Schmidt, M. Gilbert, and H. G. Johnson. $19.95

Begin making plans to attend the

Eighty-eighth
Annual Meeting of The American Economic Association

to be held in

DALLAS, TEXAS

Sunday, Monday, Tuesday

DECEMBER 28-30, 1975

The Employment Center opens Saturday, December 27.
This is a change from the October dates previously announced.

See the Notes section of the September, AER for the preliminary program.

The 1976 meeting will be held in Atlantic City, September 16-18.

Bank Management and Portfolio Behavior

Donald D. Hester and James L. Pierce

Based on a rich body of confidential data on 400 New England banks giving deposits and asset holdings quarter by quarter for a four-year period, this book provides a microeconometric analysis of portfolio behavior and earnings by commercial and mutual savings banks. Cowles Foundation Monograph 25 $20.00

Agricultural Research and Productivity

Robert E. Evenson and Yoav Kislev

The first effort to probe deeply and systematically into the role of agricultural research in producing the type of technology change that can substantially affect food production and the global food problem.

"Makes a major contribution to our understanding of the role of agricultural research in economic development."—D. Gale Johnson

A Publication of the Economic Growth Center, Yale University, in association with the World Bank Cloth $12.50 Paper $3.95

Multinational Firms and Asian Exports

Benjamin I. Cohen

The conventional wisdom holds that developing countries benefit when foreign firms establish plants that produce and export manufactured goods. This monograph by Benjamin Cohen is a searching analysis of that assumption, which the author concludes is incorrect. A Publication of the Economic Growth Center, Yale University $12.50

Colonial Development

An Econometric Study

Thomas B. Birnberg and Stephen A. Resnick

This book uses an econometric model to examine the process of economic development for ten Asian, African, and Latin American countries. It shows how they were transformed in a similar pattern from about the start of the twentieth century to the outbreak of World War II. A Publication of the Economic Growth Center, Yale University $20.00

ADAM SMITH:

Man of Letters and Economist

by CLYDE E. DANKERT

author of Contemporary Unionism in the United States

This book paints a fascinating portrait of one of the most significant figures in the intellectual history of Western man, with new insights on present-day relevance. The literary, as well as the economic, aspects of Smith's career are emphasized in Prof. Dankert's collection of essays. This is stimulating reading for both the specialist and non-specialist. **$10.00**

Educated planning today leads to higher profits tomorrow.

1. ANALYSIS AND CONTROL OF DYNAMIC ECONOMIC SYSTEMS
By **Gregory C. Chow,** Princeton University

Presents a set of related techniques for analyzing the properties of dynamic stochastic models in economics and for applying these models in the determination of quantitative economic policy.

1975 316 pages $19.95

2. LOCATIONAL DYNAMICS OF MANUFACTURING ACTIVITY
Edited by **Lyndhurst Collins,** University of Edinburgh and **David F. Walker,** University of Waterloo, Canada

Original essays interpreting changing patterns of industrial location in terms of historical and behavioral perspectives as well as contemporary theories and models.

1975 402 pages $27.50

3. SOCIAL INFORMATION PROCESSING AND STATISTICAL SYSTEMS—CHANGE AND REFORM
By **Edgar S. Dunn, Jr.,** Resources for the Future, Inc., Washington, D.C.

This book analyzes the ways social data for management, public policy, and social science are acquired and processed and discusses the dilemmas this poses for those seeking to reconcile the need for individual freedom with the equally compelling need for social order.

1974 246 pages $12.50

4. SOCIAL INDICATORS AND SOCIAL THEORY
Elements of an Operational System
By **Karl A. Fox,** Iowa State University

Integrates theory, methods, and data across several social sciences, considering time budgets, behavioral setting, personality structure, occupational structures and many other areas to provide a rich theoretical perspective.

1974 328 pages $14.95

5. SPATIAL PERSPECTIVES ON INDUSTRIAL ORGANIZATION AND DECISION-MAKING
Edited by **F. E. Ian Hamilton,** University of London

Original research studies by well-known authorities focusing upon locational behavior by industrial organizations. Stresses types of industrial organization and decision-making behavior and their impact on industrial location patterns.

1974 533 pages $29.95

6. DOLLARS FOR NATIONAL GOALS
Looking Ahead to 1980
By **Leonard A. Lecht,** National Planning Association

Analyzes the changes in spending patterns during the 1960s, showing how these changes will influence a series of national goals and problems over the next decade.

1974 295 pages $17.95

7. STATISTICAL SAMPLING FOR AUDIT AND CONTROL
By **T. W. McRae,** The University of Bradford Management Centre

This book enables accountants to apply statistical sampling methods in auditing and financial control. It will help reduce the high set up and learning costs that statistical sampling incurs.

New from Columbia

EMPLOYMENT IN DEVELOPING NATIONS

EDGAR O. EDWARDS, Editor

This book presents the findings of three seminars convened to study the problems of employment in developing countries. The seminars, dealing with economic policy, technology, and rural development, were sponsored by the Ford Foundation and were designed to promote understanding for the alleviation of these problems.

cloth, $15.00; paper, $7.50

SEX, DISCRIMINATION, AND THE DIVISION OF LABOR

CYNTHIA B. LLOYD, Editor

This collection of sixteen essays looks at the role of women in the labor market, touching on the areas of productivity, participation, and compensation, among others. These essays will be valuable to the student or individual with only a basic knowledge of economics as well as to students of economic research and teachers of courses on women.

Studies in Economics, 8 cloth, $17.50; paper, $6.00

New from the National Bureau of Economic Research

THE ALLOCATION OF TIME AND GOODS OVER THE LIFE CYCLE

GILBERT R. GHEZ and GARY S. BECKER

This book is part of a growing literature on the economics of the household that views family formation, dissolution, acquisition of skills, and the use of resources as amenable to economic analysis. The authors develop a theoretical model which has wide applicability and strong explanatory power.

Human Behavior and Social Institutions, 6 $10.00

AN ECONOMETRIC ANALYSIS OF THE URBAN HOUSING MARKET

MAHLON R. STRASZHEIM

To provide an understanding of the economics of the housing market and its role in metropolitan development, the author applies econometric procedures to better assess the huge variations that exist in the characteristics and prices of available housing. A model is developed to explain the spatial variation in prices and incomes of occupants of the existing housing stock by neighborhood.

SEPTEMBER 1975

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

- Published at George Banta Co., Inc., Menasha, Wisconsin.

- The American Economic Review, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory,* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

- 1975 membership dues of the Association are $23.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature.* Junior membership at $11.50 per year is available to registered students for a maximum of three years. 1976 membership rates will be available after October 1, 1975. Subscriptions (libraries, institutions, or firms) are $34.50 a year for 1975, and only subscriptions to both publications will be accepted. Effective January 1, 1976, the annual rate is $37.50; foreign postage add: PUAS, $2.10; all other countries and Canada, $2.50. Please write the Secretary's office, Nashville, Tennessee, for single copy prices.

- Correspondence relating to the *Papers and Proceedings,* the *Directory,* advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, Rendigs Fels, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

- Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

The 1975 Report of the President's Council of Economic Advisers: Food and Agriculture

By HAROLD O. CARTER*

While *U.S.* crop production suffered the largest decrease in forty years, space devoted to a separate chapter "Food and Agriculture" (pp. 160–86) in this year's Economic Report reached record proportions. Since the inception of the Report in 1947, agricultural matters generally have been covered in subsections of chapters dealing with broader economic issues—and in about one-fifth the space. However, I resist the temptations to read greater significance into this happening than it probably warrants, having some knowledge and experience of the machinations and procedures for preparation of the Economic Report.

The focus of the food and agriculture chapter is largely on market-oriented agriculture and its interdependence with the world economy. The first section is a review of 1974 food prices, and it summarizes some of the favorable and adverse agricultural developments (pp. 160–65). The second and most lengthy section deals with long-term changes in agriculture (pp. 165–77). This is followed with a section on policy challenges and options (pp. 177–84). The chapter is concluded with a short section articulating guidelines for domestic farm policy (pp. 184–86).

I. Developments in 1974

Poor crops, substantial increases in marketing margins, and spiraling sugar prices were sighted as contributing to retail food prices that advanced at 13.4 percent annual rate between June and December 1974. For the entire year food prices rose 12.2 percent, second only to the record 20.1 percent in 1973.[1] Perhaps with discretion being the better part of valor, the Council refrained from a prediction for 1975.

Reverberations from the poor American crops were felt not only in our economy but on world markets. Indeed, our capacity to provide food aid to developing countries and even supply commercial export markets was severely tested. The Report stated: "The U.S. crop shortfall placed two new strains on the capacity to supply food aid. It first raised the opportunity costs of any given quantity of food aid, since any incremental exports would only aggrevate the adjustments required in the United States. It also raised the budgetary costs of any given volume of food aid during a period of concerted effort to hold down Federal expenditures" (p. 165). Most surely, the opportunity costs associated with food aid or even commercial exports to consumer and producer groups are different when supply is short as compared to past periods when we were disposing of burdensome surpluses.

II. Long-Term Changes in Agriculture

The Report states that since the early 1960's both the economic environment and the conditions of *U.S.* agriculture have

---

* Professor and chairman, department of agricultural economics, University of California, Davis.

[1] December to December percentage changes. See the Economic Report, p. 304.

undergone substantial change, "Excess capacity has declined, crop reserves have been drawn down, the world agricultural situation seems to have worsened, and agricultural products again appear to be subject to the unstable price conditions of an earlier era" (p. 165). While indeed some of the arguments presented in support of each of these developments is persuasive, the real question is the extent of the changes and whether they are transitory or represent permanent shifts.

Excess capacity declines in the post-World War II era are characterized by four developments according to the Report: (1) an apparent decline in the growth rate of agricultural productivity; (2) a shift from an excess supply of labor in agriculture toward a balance with demand; (3) a largely illusory acreage reserve; and (4) an expanded demand for *U.S.* output.

Consider first the apparent slowdown in growth of agricultural productivity. Total factor productivity (farm output per unit of total input) as measured by the U.S. Department of Agriculture (USDA) increased over each of the last three decades. During the 1950's it increased 27 percent compared to only 11 percent in the 1960's. The Report summarizes: " . . . The extent to which the dramatic decline in productivity growth in the 1960's represents a real and enduring decline is not clear, but the answer is of critical importance to the future trends of U.S. and world food supply" (p. 167). Serious questions have been raised over methods of measurement of agricultural inputs and outputs. A recent report of the National Academy of Sciences on "Agricultural Production Efficiency" cautioned considerable care in interpreting the trends in farm productivity or efficiency. Substantial revisions were apparently made by the USDA between 1971 and 1972. These changes operated to largely eliminate the apparent period of stagnation in efficiency exhibited in reports issued in 1971 and 1972. Admittedly, difficult conceptual and data problems exist in productivity measurement. The National Academy report notes several of these difficulties, including failure to reflect changes in quality of inputs. The case of labor is one example. No account has been taken of the substantial increases in the level of education of the farm labor force that has occurred over the past decade, or the changes in age and sex distribution. In conclusion, the National Academy report states "The available measures of inputs and outputs for U.S. agriculture are presently inadequate to provide evidence on the changes in the efficiency of agricultural production" (p. 38).

Excess labor in agriculture and income disparities between the farm and nonfarm sector according to the Report " . . . appear to be nearing an end" (p. 167). Support for this conclusion is drawn from farm employment and farm population data, both of which show a much slower rate of decline in the 1970's compared to the 1960's and 1950's. However, the Report contained some caution about overstating farm population which includes people residing on units officially defined as "farms." Changing life styles that make rural residences more attractive —not to mention changing census definitions of farms—may well be distorting our "true" farm count. Comparison of family farm and nonfarm incomes between 1970 and 1973 show a narrowing differential. "In 1970 the median income of farm families was about $3,700 less than that of nonfarm families; by 1973 the differential had been reduced to about $2,100" (p. 168). Extrapolations of such trends may overstate the closeness to equilibrium because 1973 was an unusually good year for agriculture. Moreover, another important dimension for shaping future farm policy is the distribution of income, within and between regions, which is not mentioned in the Report.

The agricultural reserve capacity attributed to land being withheld for production by government programs was generally assumed to be 60 million acres or about one-sixth of the nation's cropland. This has been referred to as illusory land reserve or "phantom acres" because they were not all returned to production after the federal acreage set-aside program was relaxed in 1973. In 1973 only 28 million additional acres came back into production. In 1974 farmers reported intentions to plant 17 million acres more but for various reasons including bad weather they expanded by only 9 million acres. Because of crop failures, cropland harvested was only 4 million acres more than in 1973. Thus, the Report points out that between 1972 and 1974 crop acreage rose by only 37 (28+9) million acres, suggesting less excess capacity than generally believed. The USDA's Economic Research Services indicate that crop prospects for 1975 suggest another 12 to 16 million acres coming into production, provided decent weather and prices prevail. The question of how much additional land could be brought into production generally brings forth a wide range of answers. To some, potential arable land refers to productive capacity or ultimate limits of land development without regard to cost or benefits. To others it is some unspecified point on the land development schedule, with assumed (but usually not clearly stated) levels of technology and prices. A USDA report provides estimates of how much *U.S.* land is suitable for crop cultivation. Of the total amount of the top three soil classes (I, II, and III), 365 million acres (58 percent) were being used as cropland and 265 million acres (42 percent) were in other uses (mainly forest and grass), but were considered suitable for regular cultivation. The 265 million acres of potential cropland was stratified according to feasibility for reclamation. They estimated about 152 million acres have high or medium potential for conversion to cropland.[2] While recognizing that agriculture is a land based industry, it is equally important to note that food output increases have come about from both intensive and extensive land use. The United States and most other developed countries have relied in modern times more on nonland inputs than on inputs of land to increase output. Thus, the concern expressed in the Report from a possible overestimate of excess land capacity because 23 million acres have been slow to reappear seems somewhat overstated.

The effects of increased demand for agricultural products as contributing to the reduction in excess agricultural capacity is discussed in the Report at some length. The volume of exports averaged 39 percent higher in the 1972–74 period than in the previous three years (fiscal basis). Again the real question is how much of the increase is temporary—due to poor world crops, two devaluations, and various market aberrations—and how much is of a more permanent nature and will continue as part of an upward trend? Even though agricultural exports for the fiscal year ending in June 1975 are forecast to reach a new record high of $22 billion, the volume of items shipped will likely be down by as much as 10 percent.

No mention is made of how much domestic demand for agricultural products will be affected by increased energy prices to the extent that those prices affect economic growth rates, general price levels, and income distribution. Some of our biggest commercial markets have scaled down orders as growth rates have slowed and declined in some cases. Japan and the United Kingdom suspended beef imports for short time periods. Other buyers have attempted to reduce trade deficits through cancellations, deferrals, and resales of food commodities. The effects from increased energy prices on those markets that exist in developing countries is more serious. A USDA report (1974) estimated that imports of petroleum, food, and fertilizer cost the developing countries $15 billion more in 1974 than in 1973. Of this total, oil import costs are expected to account for $10 billion, an amount roughly equal to developing nations' increased commodity exports during the past two years.

---

[2] This acreage was further divided into short-run and long-run. Short-run acreage (about 63 percent of the total) could be converted to crop uses virtually from one year to the next and long-run acreage would require construction of works of improvement and this takes a longer period.

The second subsection under "Long-Term Changes in Agriculture" is concerned with "A Changing World Agriculture" (pp. 170–72). The Report summarizes succinctly the world food-population balance controversy. While much has been written on this topic pre- and post-World Food Conference, the Report takes a middle-of-the-road position in terms of prospects for feeding an expanding world population. Three troublesome developments in world agriculture are noted: (1) a decline in the growth rate of world agricultural production; (2) a reduction in the supply of new land that can be brought into production, at least at supply prices of the past; and (3) the increased dependence on the United States as a supplier of agricultural products. The latter development is particularly alarming. "As recently as the late the late 1930's, North Africa, the Middle East, and Asia were net exporters of grains. Now these regions are consistently net importers. Similar trends elsewhere have made the United States the dominant exporter of grains, responsible for more than 50 percent of the total" (p. 172).

The Report (pp. 173–77) cites a number of factors to suggest that the *U.S.* food and agriculture sector has now entered a period of greater price instability: (1) large stocks held previous to 1972 provided a stabilizing influence on the market; (2) land reserve held in the 1950's and 1960's provided a further buffer offsetting changing conditions of supply and demand; and (3) there are expectations that an increasing share of *U.S.* output will go into export markets and thereby expose the agricultural sector to the vagaries of the world market. Fluctuations in world markets stemming from domestic policies of the European Community and Japan, and *USSR*'s growing involvements in world trade have exacerbated the effects on *U.S.* markets according to the Report. The Report notes that measures of variability for four important commodities (wheat, corn, beef cattle, and hogs) declined in almost every case comparing the 1910–49 period with 1950–71. For reasons not entirely apparent, the Report states that: "Without a significant rebuilding of stocks, more price instability should be expected than during the 1950's and 1960's, but it seems unlikely that year-to-year changes will be as large as in the earlier era" (p. 177). J. P. Houck's study on agricultural regulations and stabilization noted that individual prices of wheat, corn, soybeans, and cotton became more variable in the 1960's compared to the 1950's. He attributed this change to "market oriented" commodity programs and the use of direct income supplements to support farm income for producers of the key commodities. In any case, it would seem that we have too few observations in a period of conflicting events to generalize future trends with much confidence.

III. Policy Challenges and Options

The challenges are summarized under Agricultural Development, the Instability Problem, and Food Assistance. Under

Agricultural Development, the Rome World Food Conference is the lead item, but no assessment is given as to what it accomplished or what positive benefits can be expected in its aftermath. Certainly the dire predictions that were made by many notables at the opening last November that millions of people would die of starvation before mid-1975 have proven to be exaggerated. In fact, we have seen several months of declining food grain prices. This is not to imply complacency about a most severe food-population problem, but rhetoric won't solve it. The Report correctly focuses on the importance of developing and disseminating new production technology that will have a high rate of social return in the developing countries. Like the Rome Food Conference, the Report takes the less controversial course and avoids issues of population growth.

Grain reserves are discussed in the Report as one of the ways to alleviate the instability problem in agriculture (p. 180). There is some doubt expressed even to its need for that purpose if success is achieved in getting (1) improved worldwide information and analysis, (2) coordination with other countries of domestic agricultural policies, and (3) trade liberalization. The Report concludes that there are two reasons why the United States should build grain stocks above their current low levels. First, contingency reserves could furnish some price protection to *U.S.* consumers and producers (especially livestock producers). Second, it would guarantee our foreign customers steady access to supplies. Another reason not discussed would be to guarantee supplies of concessionary food aid to meet short-term emergencies in developing countries.

IV. Guidelines for Domestic Farm Policy

The principle enunciated in this section largely repeats what had been included in various Reports since 1970. That is to move toward greater market orientation with price supports below market clearing levels, limited production controls, if any, and direct cash payments, if needed. Yet it must be recognized that adherence to these principles is politically easier in periods of high agricultural prices and short supplies. President Ford vetoed recently a farm bill that would substantially have raised the target prices of the main commodities. While the veto was sustained this time, still lower prices would provoke another attempt with a better chance of success. Thus, until the question is answered of whether the economic environment in which the agricultural sector operates has substantially changed, it seems premature to "bury" land diversion, government payments, export subsidies, import restrictions and even mandatory production controls, no matter how appealing that option may be.

V. Concluding Comments

The chapter as a whole is well done and comprehensively summarizes most of the major issues and development in a "market oriented" agriculture in a world economy. It tries a bit too hard to establish the fact that "American agriculture finds itself in the mid-1970's at a watershed" (p. 165). From the title "Food and Agriculture" one might have expected more emphasis on food policy and less on farm policy per se. Some further recognition of the effects of agricultural and trade programs on consumer food prices as well as the viability of the agricultural sector would have been in order. The organization of the chapter leads to some repetition. For example, price instability is discussed as major subsections under two main sections. Similarly, agricultural development issues are treated in several sections with some overlap. Interestingly, only passing mention is made of the impact of increased energy prices on agriculture. Yet, President Ford

The 1975 Report of the President's Council of Economic Advisers: Long on Analysis, Short on Policy

By WILLIAM POOLE*

The Annual Report of the Council of Economic Advisers (*CEA*), which appears every year in late January or early February, is in many respects a peculiar political document. The function of the Report is in part to present the president's economic program, and in part to present the views of the *CEA* and its staff, a group of economists working in government for a few years and typically on leave from university appointments. There seems to be a tacit understanding that it is perfectly acceptable for the *CEA* to publish almost any academic views, irrespective of their political implications, and that what really counts are the explicit policy proposals.

This schizophrenic separation of the actual policy recommendations from the policy recommendations clearly implied by the general analysis is particularly evident in the 1975 Report. That the policy recommendations fall so far short of the analysis is probably due to a new president's difficulties in quickly putting together an economic program and to the fact that the policy implications of the *CEA*'s analysis are further removed than usual from what seems to be politically feasible. It is certainly not difficult to sympathize with the *CEA*, especially now that current political realities appear to leave it with relatively little real power. Having said all this, however, it is still the function of the economist-critic to discuss the economics and not the politics.

Besides the schizophrenia referred to above, two other features of the 1975 Report are noteworthy. One is the extent to which micro and macro issues are intertwined, and the second is the extent to which short-run policy prescriptions are dictated by long-run considerations.

In keeping with these introductory comments, the discussion below is divided into two major sections, one on the *CEA*'s macro analysis, and one on its policy recommendations. At the end are a few concluding comments.

I. Macro Analysis

The *CEA*'s macro analysis is contained in separate chapters on inflation and unemployment, and in bits and pieces in the chapters on the 1975 outlook, the 1974 review, and the appendix on the Economic Stabilization Act. By pulling together the pieces of analysis scattered throughout the Report, a coherent view of *CEA* attitudes on inflation and unemployment can be obtained.

A. *Inflation*

The *CEA* clearly accepts the monetary explanation for long-run inflation: "Rapid and sustained inflation requires a continual inflationary increase of the supply of money" (p. 131). This argument is repeated several times in different ways. Moreover, the argument that budget deficits create long-run inflation is explicitly rejected: "Yet price inflation caused by deficits with unchanging money supply would be of limited significance" (p. 131). Supporting the monetary explanation is a table (p. 133) showing inflation rates and money growth rates for 1965–70 and 1970–74 for the United States and five other developed countries.

---

* Brown University.

A monetary explanation for inflation would appear to place the responsibility in the lap of the monetary authority, and the *CEA* does not shrink from this conclusion. "Considering that our monetary authority, the Federal Reserve System, creates the quantity of reserves which is a basic determinant of how much money can be created in addition to hand-to-hand currency, one is led to ask why the regulation of the money supply has not prevented these undesirable price trends" (p. 133). Two paragraphs are then devoted to the argument that the Fed is not able to control money growth very precisely, but this argument is rejected.

> Nevertheless, the long-run growth in monetary aggregates is determined largely by the rate at which the monetary authority injects "high-powered money," . . . into the system. . . .
>
> . . . .
>
> The question therefore remains why the Federal Reserve System did not prevent this sustained period of steepening inflation. [p. 134]

Two reasons are given to answer "the question that remains." One is that the Fed financed part of the budget deficit and borrowings of federal credit agencies with monetary expansion . . . "Partly to avoid a tightening of the market to other borrowers . . . " (p. 135). The second reason for the high rates of monetary expansion . . . "was the effort of policy makers to play safe against recessions . . . " (p. 135).

Following this discussion, and complementing the analysis of the Phillips curve in the preceding chapter on unemployment, is a section on "The Unstable Tradeoff" (pp. 136–41). The thrust of this argument is that there is no long-run tradeoff between inflation and unemployment, although there may be a short-run tradeoff due to lags in price adjustments. This discussion, along with comments on the deficiencies of wage and price controls, has as its basic message that we had better take our medicine now: " . . . there is always a choice between accepting the difficulties of adjustments 'now' or moving toward even greater future difficulties" (p. 137).

The *CEA* analysis of long-run inflation is correct; prices could not have risen so rapidly without the monetary expansion, and the monetary expansion was under the control of the Federal Reserve. The validity of the analysis of the reasons for the excessive monetary growth is less clear; it is always more difficult to discuss motives than facts. It might, however, have been useful for the *CEA* to sidestep the question of what motives were in fact operative by concentrating on the effectiveness of the actual policies. The argument that the long-run Phillips curve is vertical makes clear that excessive monetary expansion is not in fact an effective way to "play safe against recession." Similarly, the Council mentions that high monetary expansion is not an effective way " . . . to avoid a tightening of the [credit] market to [nonfederal] borrowers . . . " (p. 135), but the point deserves a more extensive treatment, perhaps along the lines of the Phillips curve analysis, to show that as inflation develops it is only a matter of months before interest rates end up higher than they would have without the extra monetary expansion. Since the interest rate peak is ultimately higher, the damage to interest-sensitive markets such as the mortgage market is actually exacerbated rather than eased by Federal Reserve efforts to hold interest rates down.

Another point of interest in the *CEA*'s analysis of inflation is its clear discussion of the impact of inflation on federal tax revenues. In the review of 1974 (ch. 2), it is noted that " . . . from the first quarter of 1973 to the third quarter of 1974 the full-employment surplus rose by $35 to to $36 billion" (p. 63). Most of this increase is attributed to the effects of inflation, and at the end of the chapter on inflation there is a fairly detailed analysis of the features of the tax structure that give rise to the high elasticity of revenues with respect to inflation.

While most of the analysis concerns inflation in the long run, there are a few comments concerning the causes of inflation in the short run. The thrust of the argument is that special factors may change the timing but not the ultimate extent of price rises caused by excessive money growth. Among the special factors mentioned as having some importance in 1974 were the end of wage-price controls and the end of fixed exchange rates. These factors are mentioned as specific examples of a more general lag phenomenon. Although the noneconomist will probably not find the exposition very clear, the *CEA*'s position is that rising unemployment can be expected to be associated with a price deceleration, so that the lags are to be interpreted in terms of changes in the rate of inflation rather than in terms of the price level itself. Moreover, the *CEA* argues that the price decelerations associated with recessions have become steadily smaller over the postwar years, the implication being that progress in reducing inflation will be slow and painful.

The inflationary contribution of the Organization of Petroleum Exporting Countries (*OPEC*) is mentioned, but underplayed. The impact of the *OPEC* cartel on the aggregate price level is said to be "substantial" but no effort is made to pin much of the blame for recent inflation on *OPEC*.

B. *Unemployment*

Chapter 3, "Unemployment," is substantially longer than chapter 4, "Inflation During the Last Decade," and to my tastes less interesting. While the Council says that "This chapter is intended to be a guide to the formulation of constructive policies toward unemployment over the long run" (p. 86), the guidance offered is almost entirely in terms of explaining the meaning and interpretation of the data rather than in terms of an analysis of the causal factors involved and of the policies required. The measurement of unemployment in the United States is explained, and *U.S.* figures compared to those in other developed countries. Unemployment is categorized into frictional, structural, seasonal, and cyclical components. The concepts of duration per spell and number of spells per worker are explained. Unemployment in age, sex, student/nonstudent, veteran/nonveteran, educational attainment, and race categories is described. Finally, there is a brief description of the major income maintenance programs.

While most of the chapter on unemployment involves a description of the data, two analytical themes are prominent. The first is that there is no long-run tradeoff between unemployment and inflation, even after adjusting for changes in the demographic composition of the labor force. The second theme—one that appears in scattered comments rather than in an integrated argument—is that many government programs add to the level of unemployment. Mentioned are minimum wages (p. 107), state equal pay laws (p. 113), and unemployment benefits (pp. 121, 123–24).

The big disappointment in the chapter on unemployment is the utter lack of any discussion concerning the causes of the current recession; the *CEA*'s silence on this issue is in sharp contrast to its analysis of the causes of long-run inflation. In the light of the popular view that recessions are the result of inherent instability in the private sector, it would have been very useful for the *CEA* to have emphasized the fact that the current level of unemployment is the direct result of low monetary growth in 1974 following high monetary growth in 1972–73 and a huge rise in the full-employment budget surplus in late 1973 and 1974. Once the policy mistakes of 1972–73 had been made, a recession of some sort was perhaps inevitable, though the 1974 policies exacerbating the contraction were not. In any event, whether one emphasizes the policy mistakes of 1972–73, or of 1974, it is clear that recessions of the current magnitude are made in Washington, not New York, Detroit, Chicago, or Los Angeles.

II. Macro Policy Proposals

If the *CEA* Report had been written as I have written about it—a section on analysis and a section on policy—the reader would have come to the policy section expecting to discover a substantial list of policy programs. After finishing the Report what he discovers instead is an extraordinarily meager policy program.

The stabilization program—along with the energy proposals—is presented and defended in one short chapter (ch. 1, "Economic Policy and Outlook") of 15 pages. There is no point in presenting a detailed examination of the proposals; they were generally recognized as being obsolete six weeks after the Report was issued. In outline, the policy proposals involved: a) an excise tax of $2 per barrel applied to both domestic and imported oil and an equivalent tax of $0.37 per thousand cubic feet on natural gas; b) reduction in individual and corporate income taxes just offsetting the new energy taxes; c) temporary tax cuts in the form of a one-year increase in the investment tax credit and a tax rebate for individuals of 12 percent of their 1974 tax liabilities, up to a limit of $1,000 per return.

It is interesting, and probably unfortunate, that the stabilization and energy policies are discussed together. The association of the two tends to mix up stabilization issues with micro issues, but this mixing was perhaps inevitable once the decision was made to deal with the micro problems by levying new taxes large enough to have macro implications.

The *CEA* did not expect much of a stabilization effect from this modest program. It was estimated that the program would cut the extent of the forecasted year-over-year decline in income in 1975 " . . . one-half of 1 percent to 1 percent in terms of real GNP" (p. 20). This stimulus, by Okun's Law, amounts to 1/6 to 1/3 of a percentage point of unemployment. Given the forecast that " . . . the unemployment rate should average about 8 percent for the year . . . " (p. 27), it is clear that the *CEA* felt unwilling or unable to recommend fiscal policies that promised to do very much.

The small fiscal program did not, it is clear, stem from an assumption that monetary policy would do the job. In contrast to the 1971 Report, where it was argued that "with the proposed budget and complementary monetary policy," a *GNP* in the neighborhood of $1065 billion was a "reasonable expectation" (p. 85), nowhere in the 1975 Report is there a clear statement that a monetary policy assumption is needed to generate the near-term economic forecast.[1] The contrast with the *CEA*'s explicit discussion of the role of monetary policy in long-run inflation is so great that a rather lengthy quotation is in order.

---

[1] The *CEA* does, however, use language suggesting that it may favor a more expansionary monetary policy. It says that "one way" of preventing federal deficits from crowding out private investment would be to increase the rate of money growth and that in a substantially unemployed economy ". . . an increase in monetary growth need not be inflationary in the short run . . ." (p. 25).

> Monetary policy faces great difficulties in the year ahead and will require careful and continuous evaluation by the Federal Reserve. The uncertainties that underlie the outlook for 1975 add to the importance of a flexible monetary policy. Monetary policy must be conducted so as to encourage near-term recovery in the economy and a resumption of sustainable economic growth. Toward this end, reasonable growth in money and credit will be required—growth which, one hopes, will encourage a freer flow of credit and lower interest rates in private credit markets. Whether more accommodating credit conditions will in fact develop depends importantly on the ease with which the enlarged Federal deficit is financed, and also on the progress that is achieved in moderating the Nation's rate of inflation as 1975 progresses. [p. 26]

This nonstatement is inconsistent with views expressed elsewhere in the Report. Not only is the analysis of long-run inflation quite explicit on the Fed's role, but in chapter 2, reviewing the events of 1974, the *CEA* says that, "Growth rates in monetary aggregates and in total spending tend to move in similar patterns . . . " (p. 66). In this same chapter the sharp decline in money growth in the second half of 1974 is noted; in addition, the *CEA* says that a " . . . slightly more expansive set of monetary actions. . . . [is] expected to show soon in the monetary aggregates" (p. 67).

Neither this Council nor any previous one has been willing to face up to the issue of what happens when monetary policy is inappropriate, however judged by the particular Council. In the light of the Federal Reserve's admitted power to generate boom or bust, the unwillingness to take on the Fed is peculiar. The standard *CEA* position must reflect the Fed's extremely strong political position and the expectation held by each Council that the Fed will follow sensible policies. But it seems inevitable that a time will come when a Council, or a President, or a Congress, will take on the Fed if the Fed's performance continues its past pattern.[2] Whatever the abstract merits of an independent monetary authority, independence is in fact doomed if money growth always turns out to be high during inflation and low during recessions.

In the 1975 Report the *CEA* is obviously not expecting a continuation of the low monetary growth rates of late 1974, but neither is the *CEA* calling for any real monetary stimulus. Indeed, the general tone of the Report is that policy instruments should not stray far from the settings consistent with long-run price stability. It is understood, and accepted, that such policy settings will produce a long period of above-normal unemployment. The reasons for the *CEA*'s acceptance of a long period of slack are not entirely clear, but they seem to involve a mixture of economic and political considerations. The two economic arguments against a more expansionary fiscal policy are that " . . . a too expansionary budget carries the risk of worsening the inflation . . . " (p. 24), and that deficit financing will crowd businesses out of the financial markets.

The first argument is certainly correct if what is meant is that more expansionary policies will make the rate of inflation higher than it otherwise would have been. The noneconomist, however, would probably interpret the language used as involving the argument that more expansionary policy runs the risk of making inflation higher than it was last year. With the unemployment rates projected by the

---

[2] In early 1974 Congress took a mild step in the direction of greater control over the Federal Reserve by passing House Concurrent Resolution 133 which requires periodic reports by the Federal Reserve to Congress on monetary policy plans.

CEA this argument would seem untenable. There is no effort in the Report to examine the issue of how fast inflation ought to be reduced.

The second argument made against a more expansionary fiscal policy—the crowding out argument—appears incorrect within the context of the conventional Keynesian model in a time of extensive unemployment. For a given investment demand function and a given rate of money growth, the effects on real *GNP* of a more expansionary fiscal policy will be partly but not completely offset by a decline in private investment. Expansionary fiscal policy raises both real income and nominal interest rates. Moreover, in the conventional model the rise in income would, through the investment accelerator, cause the investment demand function to shift out, further increasing both income and interest rates. This latter argument might be especially important if the slack in the economy had pushed many firms close to bankruptcy. Loss of creditworthiness is surely a much greater threat to financing new investment than is a small rise in interest rates.

Is there anything wrong with the conventional argument? The *CEA* itself accepts the conventional argument as applied to past recessions but not as applied to the current one, the difference being that financing demands are said to be greater in inflationary conditions. Perhaps what the *CEA* has in mind is a proposition that the money demand function is highly interest inelastic under inflationary conditions so that, with a given investment demand function, an expansionary fiscal policy produces a relatively large increase in interest rates and a relatively small increase in income. In this case, for firms already overburdened with debt, the impact of rising interest rates might outweigh the favorable effects of rising sales, thus forcing weaker firms into bankruptcy and generating a depressing wave of business and investor pessimism.

Another possibility is that investment demand is more interest elastic in inflationary than in noninflationary conditions as suggested by the argument that, "As the desired private refinancing is made more difficult by the deficit financing, businesses may abandon investment projects more readily than in the past, rather than risk further unbalancing their capital structure and increasing their credit market exposure" (p. 25). To the extent that this argument is correct, an expansionary fiscal policy will not raise interest rates very much—only a small increase will be required to crowd out private investment—nor will fiscal policy be of much value in reducing unemployment. However, if the deficit were smaller and interest rates lower, would firms be willing to "further unbalance their capital structure" in order to raise debt capital to finance new investment? The logic of the argument would seem to require that federal deficit financing crowd out private equity financing.

While I am not convinced by the argument that fiscal policy is less useful under inflationary conditions, I would add that the *CEA* is probably correct in not expecting much benefit from a more expansionary fiscal policy. The crowding-out argument has increasing force as the time horizon is extended. The initial stimulus from fiscal policy is offset, either entirely or mostly, later on. If weak private demand is likely to continue for five years—a not unreasonable projection—then fiscal policy is probably not the key to stabilization policy at this time. It may well be useful to have some fiscal stimulus now in order to limit the depth of the recession, but such stimulus, even if continued, will make little difference to the unemployment rate, and possibly even make the rate higher than it otherwise would have been, three years from now. Monetary policy could make more of a difference three years from now, but only at the cost of generating a higher inflation rate than otherwise would have occurred. For a given course of policy, the key to guessing what will happen is the speed with which inflation—and the expectation of inflation—declines. Great trouble can be caused by a 5 percentage point decline in the rate of inflation, whether from a starting point of 10 percent inflation, or of price stability. In recent years firms and households have committed themselves to a tremendous amount of debt bearing high nominal rates of interest; the *ex post* real rate of interest on this debt will be painfully high if the rate of inflation adjusts downward quickly.

What the *CEA* does not make clear is that the policy issue is not one of more or less, but of more now or more later. There is, of course, no law of "conservation of unemployment"; the total man-years of unemployment over the next ten years is not a constant and there may well be a positive, or negative, return to taking unemployment in one big lump now rather than gradually over a period of time. But an important element in the policy problem is that of trading off present against future and the *CEA* would have performed a public service by following its analysis of the lack of a long-run tradeoff between unemployment and inflation with an analysis of tradeoffs between present and future.

In addition to the arguments already discussed, another *CEA* reason for rejecting a more expansionary fiscal policy is almost certainly a deep concern over the rising share of *GNP* taken by government. This position is expressed most clearly in the President's Report where it is asserted that total government expenditures now amount to one-third of *GNP* and have been growing at a rate such that in twenty years government will take one-half of *GNP*. "Spending on this scale would require a substantial increase in the tax burden on the average American family. This could easily stifle the incentive and enterprise which is essential to continued improvements in productivity and in our standard of living" (p. 4).

The micro issue of the allocation of total output between the government and private sectors frequently intrudes into the macro issue of stabilization policy. Such an intrusion is not surprising—tax changes for stabilization purposes are almost invariably delayed by arguments about who should benefit or who should lose—but in this case the statement in the President's Report is seriously misleading. The share of total government purchases, in contrast to expenditures, in *GNP* in 1974 was 22 percent, up from 20 percent in 1960, and actually down from 23 percent in 1968. Moreover, the projections of government purchases contained in the 1970 Report (Tables 13 and 14, pp. 79, 80), converted to 1974 dollars were for state and local government purchases only $0.7 billion below the 1974 actual, and federal purchases $17.2 billion *above* the actual.

The real issue is the rapid growth of total government transfers to persons. In 1974 these transfers amounted to 10 percent of *GNP* and 12 percent of personal income, up from 5 percent and 7 percent, respectively, in 1965. Actual federal government transfers to persons in 1974 were $18.4 billion (19 percent) above the projections for 1974 made in the 1970 Report, and the projections had already included an allowance of $6.6 billion for the Family Assistance Plan of welfare reform.[3]

Transfers do not per se increase the net burden of taxes less transfers for the average family, but they may have significant disincentive effects. For those whose disposable income is raised the disincentive effect may be substantial since the income effect and the substitution effect generated by higher marginal tax rates both work in the same direction. As noted earlier, the *CEA* in its discussion of unemployment did mention the disincentive effects of some income maintenance programs.

---

[3] The 1970 projections for transfers were converted to 1974 dollars using the personal consumption deflator.

Income maintenance programs have grown so rapidly in recent years—a growth that is likely to be extended and accelerated by the current recession—that Congress will have to take up the issue of welfare reform once again. With government transfers amounting to 12 percent of personal income in the context of a poorly designed set of programs, the disincentive effects may well be large enough that welfare reform should be treated as having substantial macro implications—implications for aggregate real *GNP*—as well as the obviously important humanitarian and distributional implications. It is disappointing that the *CEA*, in the light of its concern over the problems of incentives and excessively rapid growth of government spending, did not produce a better analysis of the issues involved.

III. Concluding Comments

The *CEA* presents essentially no program for dealing with the current recession. There is no explicit analysis of how the current recession came about, and no analysis of the choice that must be made between the speed with which inflation is to be reduced and the speed with which unemployment is to be reduced. If the *CEA* rejects the notion of a short-run tradeoff under present conditions—an argument that, whether right or wrong, certainly could have been made—then it should have presented the details of a positive case for not following expansionary policies under current circumstances.

The *CEA* analysis clearly demonstrates the need for long-run reforms in the way macro policy decisions are made, but no program of reform is offered. One proposal for reform might have been the adoption of a presumptive norm for monetary expansion. For example, the norm might be 3–5 percent growth for M_1, or 4–6 percent for M_2, to be breached only upon an explicit policy decision that circumstances require a departure or that the long-run norm must be changed. It would also have been possible to present a lengthy list of reforms for improving the accuracy of monetary control.

Fiscal reforms are also urgently needed. As noted earlier, the welfare reform issue must be faced again. From the *CEA* analysis of the effects of inflation on government revenues, it is clear that indexing of the tax system would be desirable. Indeed, the *CEA* says that "... individuals and corporations alike are now exposed to substantial and haphazard tax-raising effects produced by inflation, even during a period of falling real incomes ... adjustments in tax laws will be called for during the gradual process of price deceleration toward which we are heading" (p. 145).

Yet in the very next paragraph the *CEA* rejects such adjustments on the grounds that larger federal deficits will increase strains in the credit markets and thereby add to pressures on the Fed for higher monetary expansion. But surely, if the *CEA* analysis is correct, an indexed tax system that stabilized the full-employment surplus and prevented unforeseen inflation from generating unforeseen and unintended changes in fiscal policy is consistent with a rapid reduction in actual deficits as the recovery proceeds.

The lack of interest in long-run reforms in macro policy does not, apparently, reflect a general unwillingness to propose long-run programs. The *CEA* does discuss long-run proposals in the areas of energy, government regulation of industry, and agriculture, with separate chapters being devoted to analysis and policy proposals in the latter two areas.

The unwillingness of the *CEA* to present a package of reforms in the macro area reflects two failures in macro policy analysis in the economics profession in general. The first is that the advocates of discretionary policy have generally refused to be pinned down on formulations of optimal policy reaction functions. Policy makers are too often encouraged to respond "flexibly" in an "appropriate" fashion to the current "needs" of the economy.

There is no hope of improving discretionary policy without the explicit specification of policy reaction functions that are to be followed until evidence accumulates that better policies are available. If the policy record is to be evaluated so that past mistakes can be avoided in the future, then the policy problem cannot be viewed as one of coping with events unique in time and place. The extent to which policy makers place their bets in accordance with the objective probabilities in inherently uncertain situations cannot be judged if each situation is viewed as a separate drawing from a separate probability distribution; the probabilities in a stochastic process can never be determined from single outcomes.

The second general failure of macro policy analysis—one that apparently troubled the *CEA* in its 1975 Report—is that of presenting the basic policy issues in such a way that they can be understood by the general public. Macro policy is determined not by economists but by the political process. The destabilizing nature of monetary and fiscal policy on average since the Employment Act is not the result of perfidity but of ignorance. Congress and the general public simply do not understand the consequences of monetary and fiscal actions. In numerous places in the 1975 Report the *CEA* seems to back away from the policy implications of its analysis out of a fear that sensible proposals might be bent in directions that will make us worse off than if we do nothing. How, for example, can advocacy of a smaller government in the long-run be consistent with advocacy of government deficits now? How could advocacy of rapid money growth now be consistent with advocacy of slow money growth later? It is to be hoped that future *CEA* Reports will meet these issues head-on, as some of the past Reports have on some issues, because surely the major gains in macro policy in coming years will come from applying what we already know rather than applying the latest findings appearing in the professional journals.

Interest and Credit in General Equilibrium with Transactions Costs

By JÜRG NIEHANS*

It has long been recognized that the key to a better understanding of the services of money in general equilibrium is a theory of market imperfections or "frictions" (see, for example, John Hicks). There has been a growing interest in monetary exchange models in which market imperfections appear in the form of transactions costs (see F. H. Hahn (1971b), Mordecai Kurz, Kevin Sontheimer, Ross Starr, Edi Karni). Progress has been made in analyzing the efficiency of equilibrium in such models (Hahn (1973), David Starrett). However, it has not so far been possible to free the analysis from arbitrary assumptions about terminal money stocks. There is also no explicit analysis of the demand for cash balances relative to commodity stocks, interest-bearing assets and debt, nor do we know the exact conditions which in a monetary economy with transactions costs correspond to the familiar marginal rules in neoclassical models. The problems so admirably identified, but imperfectly solved, by Jacob Marschak in his 1949 paper, continue to absorb the attention of monetary theorists.

An explanation of the transactions demand for money and bonds, based on transactions costs, was offered by William Baumol and James Tobin. Edgar Feige and Michael Parkin have recently generalized this approach by allowing for the repercussions of transactions costs and portfolio income on consumption. However, they still confine themselves to optimization by a representative individual at exogenously given prices and rates of return. It is not explained who holds the cash balances and the bonds which, at a given moment, the representative individual does not plan to hold. Correspondingly, there is no effort to explain commodity prices and interest rates by the interplay of demand and supply for commodities and assets. Feige and Parkin also give no explanation of private debt, and they continue to use the *ad hoc* assumption of a regular saw-tooth profile of the excess of income over consumption on which all of their results are crucially dependent. A general equilibrium counterpart to the Baumol-Tobin approach is lacking.

The present paper combines elements of the general equilibrium approach and of the Baumol-Tobin approach to solve problems left open by each of them. The result is a general equilibrium model of a monetary economy with transactions costs, explaining the stock demands for commodity inventories, cash balances and bonds, and the supply of private credit. In contrast to the Feige-Parkin model, it satisfies the requirement that all cash balances and bonds must be willingly held by somebody at all times, and prices and bond yields are endogenously determined. It requires no arbitrary wealth constraint, and the time profile of assets is derived from the economizing behavior of economic agents. In an earlier paper (1971), I have shown that with given endowments and tastes, different exchange arrangements ranging from bilateral barter to full monetization and neutral money can be made to emerge simply by varying the transactions and storage costs. Its most serious limitation was the neglect of credit and interest. It is the purpose of the present paper to fill this gap.

---

* Professor of political economy, The Johns Hopkins University.

Section I outlines the general features of the model, describing an exchange economy in infinite stationary motion where individuals, subject to time preference, maximize the utility of consumption by holding commodities, money, bonds, and debt. Section II formalizes the non-linear programming problem of an optimizing individual, subject to the multiple constraints typical for transactions cost models; it also presents the marginal conditions on consumption, exchange flows, and stocks. The conditions for market equilibrium are specified in Section III, and it is shown that they impose limits on the admissible range of asset yields. In the final section, the model is used to derive the implications of an "optimal" money supply rule for the demand for cash balances, welfare, and the demand and supply of credit.

I. The Model in Outline

A. *Assets*

The analysis relates to an exchange economy without production. Individuals are endowed with certain quantities of consumables. To focus attention on the relationship between commodities (as a group) and financial assets, all consumables will be lumped together into one commodity or good. There are three assets: commodity stocks, money, and bonds. Bonds have the form of a standardized perpetuity. Certain aggregate quantities of money and bonds are supplied by the government, which finances its interest payments by lump sum taxes. Bonds may also be supplied by private individuals selling and repurchasing their own consols. Debt thus appears as a negative stock of bonds. It is assumed that the economy is fully monetized, using token money as universal medium of exchange.[1] There are thus two markets, one for goods and one for bonds.

The net yield of each asset consists of its market return, the capital gain or loss, and time preference. The market return on commodity stocks is negative, consisting of a storage cost expressed as a physical shrinkage. Bonds have a uniform and constant coupon r, fixed by the government and payable in money; their market return i fluctuates inversely to their price according to $i=r/p^b$. There may also be a positive market return on cash balances, fixed by the government. Capital gains and losses are created by changes in commodity and bond prices. The analysis thus incorporates the speculative motive for asset holding familiar from Keynesian models and stressed by Marschak. However, assets with positive net yields are not compatible with equilibrium, because further accumulation always pays. This problem is often evaded by an arbitrary wealth constraint. In the present model it is solved by introducing time preference as a third, "psychological" component of asset yield. The total net yield of an asset can thus be nonpositive even though there may be positive market returns and capital gains.

Despite the possible differences in the yields of different assets, portfolios may be diversified due to transactions costs. An individual will prefer commodity stocks to money balances for short periods, because the saving in storage costs is not worth the transactions costs on the exchange of commodities. For sufficiently short periods, he will also prefer non-interest-bearing cash balances to bonds, because the positive return on bonds is outweighed by the transactions costs on bonds. In a pure exchange economy, all assets have the character of transactions assets, used to "bridge the gaps" between the given time profile of endowments and the preferred time profile of consumption. Debt is an alternative way to achieve the same purpose; it is profitable whenever the resulting savings in asset-holding costs at least pay for the additional interest and transactions costs.[2] Transactions costs are assumed to have the form of commodity inputs,[3] proportional to the quantity exchanged.[4]

---

[1] These assumptions make it impossible, of course, to analyze relative commodity prices, the differences between monetary exchange and barter, and the choice between different media of exchange. For a treatment of these problems the reader is referred to the author's 1971 paper.

B. *Time and Utility*

For an analysis involving stocks, the temporal structure of the model is of crucial importance.[5] For the present model, this structure can be described as one of *infinite stationary motion*. Let time be divided into 1 . . T . . H years, while each year consists of 1 . . t . . h days.[6] The model is dynamic in the sense that things are subject to change from day to day within each year. This provides the basis for the demand for stocks. The model is stationary in the sense that nothing is allowed to change from year to year. This makes it possible to construct a counterpart to the stationary equilibrium of neoclassical models. In particular, endowments are the same for a given calendar day of each year, tastes remain the same from year to year, and the individual will be constrained to choose a plan with identical consumption, exchange flows, and stocks for the same calendar day of different years. H is infinite and foresight is perfect. We can thus visualize all decisions as being made at the beginning of time with transactions costs becoming due when the deliveries are made. The two parts in each exchange are assumed to be simultaneous; a sale of goods with deferred payment is constructed as a cash sale combined with a bond purchase. The concept of infinite stationary motion is of decisive help in explaining the indirect utility of assets, including cash balances, without arbitrary assumptions about initial and terminal stocks.[7]

Individuals maximize utility over the infinite horizon.[8] Utility depends on consumption only; money, inventories, and bonds may have indirect utility by permitting a more desirable pattern of consumption. The form of the utility function must conform to the stationary motion framework. It is thus assumed that tastes remain the same from year to year, but may vary from day to day within a given year. Let $U=U(x_1 \,.\,.\, x_t \,.\,.\, x_h)$ be the annual utility function as seen at the beginning of the year. It is assumed to be twice differentiable and to have diminishing marginal rates of substitution and positive marginal utilities. Note that the function is not additive, thus allowing for daily variations in tastes and for intertemporal substitution and complementarity, which are presumably some of the determinants of the transactions demand for assets. Utility over the infinite horizon is assumed to be the discounted sum of annual utilities. Since the individual is constrained to plans which are stationary from year to year, maximization of infinite-horizon utility is equivalent to the maximization of annual utility. As a consequence, $U(\ \ )$ is all we have to pay attention to.

---

[2] In the absence of time preference and storage costs, nobody would go into debt, since asset holding would be costless. This is the basic reason why the Baumol-Tobin approach cannot explain the supply of debt.

[3] From a fundamentalist point of view, transactions costs may appear to be largely caused by uncertainty and the consequent search for information. While these elements are important in the world as we know it, recent contributions have shown that a meaningful general equilibrium model of monetary exchange can be constructed on the assumption of full certainty. For efforts to develop an explicit analysis of search, see the papers by Karl Brunner and Allan Meltzer, and by Joseph Ostroy.

[4] It is clear that scale economies in transactions costs, depending on transactions scale as well as on market scale, play an important role in actual exchange arrangements. While such scale economies have often been prominent in models of individual optimization (as, for example, the Baumol-Tobin and the Feige-Parkin models), they are, for well-known reasons, difficult to incorporate in a general equilibrium system (for a recent contribution see Walter P. Heller). The following analysis indicates that the basic aspects of a money and credit economy do not arise from scale economies.

[5] In Hahn's (1973) terminology, one of the requirements is that the economy allows for "not inessential sequences."

[6] Flows with index t are concentrated at the *end* of day t. The paper offers no analysis of the sequence of events during the trading period of a single day. On this point see E. C. H. Veendorp and the author's 1973 note.

[7] Hahn (1973) conjectured that the assumption of exogenously given terminal stocks can be abandoned in an economy with infinite horizon and overlapping generations (p. 456). Indeed, this seems to be one type of economy capable of infinite stationary motion.

[8] To prevent a frequent error, it may be noted at this point that utility maximization generally does not imply transaction cost minimization. Nor does the transactions cost approach to monetary equilibrium maintain that the use of money lowers aggregate transactions costs. Transactions costs are indeed minimized for a given volume of transactions (as in the author's 1961 paper), but this may be more than balanced by a higher volume of transactions.

Time preference is implicit in the utility function. In particular, the derivative $\partial U/\partial x_t$, to be called the *discounted marginal utility*, depends in part on the time span between the planning moment and day t. It will gradually increase as t comes nearer. To make the role of time preference explicit, we define $\partial V/\partial x_t=(1+\theta)^t(\partial U/\partial x_t)$, to be called *marginal utility* (without qualifying adjective). It is meant to represent marginal utility "purged" of time preference, and it is postulated to be invariant as we approach it.

C. *A Graphical Illustration of Portfolio Diversification*

The diversification of assets is illustrated, nonrigorously and heuristically, in Figure 1. It depicts the annual cycle of an individual's optimal portfolio, abstracting from daily price changes, interest on cash balances, and taxes. All of its elements are jointly determined; none are exogenously given.

Endowments accrue to the individual in the form of commodities. Unless the time profile of endowments, by coincidence, matches the time profile of preferences, the individual will want to divorce the pattern of consumption from the pattern of endowments by holding assets. Total

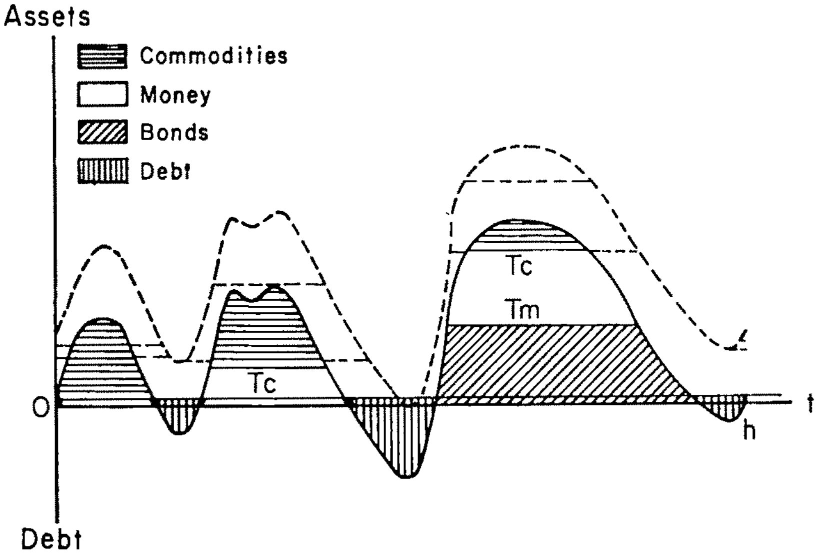

FIGURE 1

assets as a function of time are described by the solid curve. The stationarity postulate implies that this curve begins and ends the year at the same level. We assume for convenience that it begins the year at zero.[9] Total assets may, of course, be negative, indicating debt. The layers revealed in a vertical cross-section through the asset profile indicate what portions of total assets are held in the form of commodities, money, bonds, or debt, respectively, at a given moment. A horizontal section shows how long the marginal unit of an asset is held.

Commodity stocks will be held if the holding period is so short that the transaction costs for a return trip into cash balances would be higher than the storage cost. This determines a critical holding period for commodities, T_c. In the absence of transactions costs on goods, no commodity stocks would ever be held. Cash balances will be held if the holding period, though exceeding T_c, is still so short that the transactions costs for a return trip into the bond market would be higher than the market return on the bonds. This determines a critical holding period for money, T_m. In the absence of transactions costs on bonds, no cash balances would ever be held, nor will cash balances be held if $T_m < T_c$.

An individual goes into debt in order to shift his asset curve downward. People borrow to make it unnecessary to accumulate wealth. If debt had been prohibited, the asset curve might have looked as indicated by the broken line. In view of time preference and, for commodities, storage costs, this would have entailed higher holding costs. Debt thus permits a lowering of asset holding costs, but it also costs interest, both interest foregone on the interest-earning assets (if any) which would otherwise have been held, and interest paid on the debt. In addition, borrowing will often involve additional transactions costs. Debt is incurred up to the point where the marginal benefit from lower asset holding ceases to outweigh the marginal interest and transactions costs.[10] This marginal consideration can be visualized in Figure 1 by moving the vertical scale upward by $1, thus cutting off a narrow strip over the length of the asset profile. This has the following consequences: 1) It saves time preference over the length of the year, reflecting the cost of accumulating a dollar of assets; 2) it saves storage costs during the time inventories are held; 3) it costs interest (paid or foregone) during the period of debt or bond holding; 4) it adds costly transactions commodities/money/bonds and money/bonds where indicated by a heavy line (note that switching from bonds to debt adds no transactions cost). This intuitive explanation of asset diversification will be made precise and more general by the formal model.

II. Individual Optimization

A. *The Constraints*

Let an individual's endowment be described by the vector $(\bar{x}_1, \ldots \bar{x}_t, \ldots \bar{x}_h)$. The task is to transform this into the consumption vector $(x_1, \ldots x_t, \ldots x_h)$ which maximizes $U = U(x_1, \ldots x_t, \ldots x_h)$, subject to linear constraints. There are three sets of constraints, relating, respectively, to commodities, bonds, and money. In each set there is one constraint for each of h days ($t = 1 \ldots h$). The following notation will be used:

---

[9] No generality is hereby lost, because there is at least one such point in the course of the year.

[10] It never pays, in a pure exchange model, to go into debt in order to finance the simultaneous holding of assets. Compared to commodities and money, bonds are a low-cost asset. It never pays to reduce a low-cost asset by holding a negative amount of it just for the privilege of holding more higher-cost assets. It also never pays to incur transactions costs for the simultaneous holding of bonds and debt.

g = goods (in physical units)
m = money (in nominal terms)
b = bonds (in pieces of bonds)
y = quantity sold
z = quantity bought
s = quantity held in stock
p = price (in terms of money)
c = transactions costs (units of goods per unit exchanged) $(0<c<1)$
γ = storage costs on goods (percent)
r = coupon on bonds (in monetary units per bond)
ρ = interest on cash balances (percent)
t = tax (lump sum, in monetary units)

The *commodity constraint* for day t states that the increase in stocks from t to t+1 is equal to the sum of the excess of the endowment over consumption and net purchases after deducting what is wasted in storage and used up in transactions of goods and bonds:

$$(1)\quad s^{g}_{t+1} - s^{g}_{t} = (\bar{x}_t - x_t) + (z^{g}_t - y^{g}_t) - \gamma s^{g}_t - c^{g}(z^{g}_t + y^{g}_t) - c^{b}(z^{b}_t + y^{b}_t)$$

Optimization will see to it that either purchases or sales (or both) are zero for both goods and bonds. With transactions costs it is wasteful to buy and sell simultaneously in the same market. The *bond constraints* say simply that the change in the portfolio equals the excess of purchases over sales:

$$(2)\qquad s^{b}_{t+1} - s^{b}_{t} = z^{b}_t - y^{b}_t$$

The *money constraints* state that cash balances are augmented by net sales of commodities and bonds, by the receipt of coupon payments on bonds, and by interest payments on cash balances, after deducting tax payments:[11]

$$(3)\quad s^{m}_{t+1} - s^{m}_{t} = p^{g}_t(y^{g}_t - z^{g}_t) + p^{b}_t(y^{b}_t - z^{b}_t) + r s^{b}_t + \rho s^{m}_t - t_t$$

To these constraints we have to add the requirement that the stocks of commodities and money and the flows of commodities and bonds be nonnegative:

$$a \geq 0 \qquad a = x,\ y^{g},\ z^{g},\ y^{b},\ z^{b},\ s^{g},\ s^{m}$$

There is no sign constraint for bond stocks, since the individual is free to go into debt.[12] We also have to formalize the stationarity requirement, according to which an individual's choice is restricted to plans resulting in the same cycle of consumption, exchange, and stocks year by year:

$$q_{nh+t} = q_t \qquad \text{for } q = x,\ y^{g},\ z^{g},\ y^{b},\ z^{b},\ s^{g},\ s^{m},\ s^{b}$$
$$n = 0 \ldots . (\mathrm{H} - 1)$$

What an individual is asked to determine is his optimal stationary plan.

This is a non-linear programming problem with a quasi-concave objective function and linear constraints. Its solution determines the consumption of goods, the purchases and sales of goods and bonds, and the stocks of goods, money, bonds, and debt for every day, given the pattern of endowments, the history of market prices for goods and bonds, time preference, transactions and storage cost rates, taxes, the coupon on bonds, and the rate of interest on cash balances.

B. *A Two-Day Illustration*

Some intuitive insight into this optimization problem (though not into portfolio diversification) can be gained from a graphical representation (Figure 2) by shortening the "year" to two "days." The individual wishes to transform his endowment, represented by P, into the consumption plan with highest utility, given trans-

---

[11] Note that taxes may vary over time; they may, for example, be zero for every day but one.

[12] A corresponding sign constraint for bonds would express the assumption that all bonds are issued by the government.

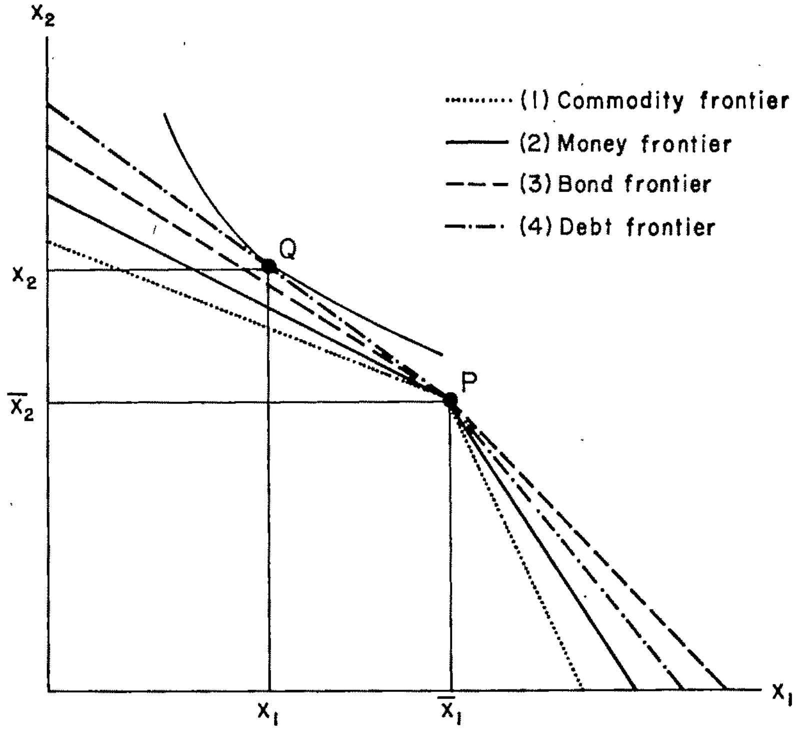

FIGURE 2

actions and storage costs and market conditions. Day 1 goods can be transformed into day 2 goods:

(a) by holding goods from day 1 to day 2;
(b) by selling goods on day 1, holding money during day 2, and buying goods on day 2;
(c) by selling goods to buy bonds on day 1, holding bonds during day 2, and selling bonds to buy goods on day 2;
(d) by borrowing to buy goods on day 2, holding a debt during day 1 of the following year, and selling goods to repay the debt on day 1 of that year.

For each sequence, the relevant constraints tell us how much x_2 can be increased by giving up a certain quantity of x_1. We thus obtain the linear segments of the commodity, money, bond, and debt frontier sloping upward from P.[18] Similar segment

---

[18] Their slopes are calculated by solving for $-dx_2/d$ from the relevant constraints, omitting those item that do not appear in the particular trading sequenc The slopes are

$$\text{(a)} \quad -\left(\frac{dx_2}{dx_1}\right)^g = 1 - \gamma$$

$$\text{(b)} \quad -\left(\frac{dx_2}{dx_1}\right)^m = (1+\rho)\,\frac{1-c^g}{1+c^g}\cdot\frac{p_1^g}{p_2^g}$$

$$\text{(c)} \quad -\left(\frac{dx_2}{dx_1}\right)^b = \frac{(1-c^g)(p_2^b+r)/p_2^g - c^b}{(1+c^g)p_1^b/p_1^g + c^b}$$

$$\text{(d)} \quad -\left(\frac{dx_2}{dx_1}\right)^d = \frac{(1-c^g)p_2^b/p_2^g - c^b}{(1+c^g)(p_1^b+r)/p_1^g + c^b}\,(1+\theta)^2$$

In sequence (d), the entries relating to day 1 of the fo lowing year have to be discounted for two days to mak them comparable with the entries for day 1 of the cu rent year in sequences (a)–(c). A comparison of the deb slope (d) with the bond slope (c) confirms nicely tha the advantage of debt, if any, is due to the time prefe ence effect, working through θ, dominating the interes effect, working through r (transactions costs being th same in both cases).

can be obtained for the reverse shift of consumption from day 2 to day 1 (of the following year), resulting in the rays sloping downward from P. Due to transactions costs, market returns, and time preference, each of the four frontiers has a convex kink at P.[14] The overall transformation frontier consists of the outwardmost segments of the commodity, money, bond, and debt frontiers. As the graph is drawn, it is efficient either to be in debt or to hold bonds during the first day. With different transactions costs, market returns, prices, and time preference, other sequences could have been efficient.[15] Once we know the transformation frontier, the optimum is determined by confronting it with the utility function. In the graph, the individual chooses Q, thereby determining all stocks and flows. If Q coincides with P, no assets are held. It is clear that in a two-day model an individual will never hold assets on both days and that his portfolio will never be diversified. With more days in the cycle, the transformation frontier will generally contain more complex sequences involving diversified portfolios.

C. *The Marginal Conditions*

More insight into the economic character of the optimal solution can be gained by deriving the Kuhn-Tucker conditions on consumption, exchange flows, and stocks.[16] They are obtained by forming the Lagrange equation

$$
\begin{aligned}
(4)\quad L = {} & U(x_1 \, . \, . \, x_h) \\
& - \sum_{t=1}^{h} \lambda_t^g \big[(s_{t+1}^g - s_t^g) - (\bar{x}_t - x_t) \\
& - (z_t^g - y_t^g) + \gamma s_t^g + c^g(z_t^g + y_t^g) \\
& + c^b(z_t^b + y_t^b)\big] \\
& - \sum_{t=1}^{h} \lambda_t^b \big[(s_{t+1}^b - s_t^b) - (z_t^b - y_t^b)\big] \\
& - \sum_{t=1}^{h} \lambda_t^m \big[(s_{t+1}^m - s_t^m) - p_t^g(y_t^g - z_t^g) \\
& - p_t^b(y_t^b - z_t^b) - r s_t^b - \rho s_t^m + t_t\big]
\end{aligned}
$$

and taking its partial derivatives. The multipliers $\lambda_t^i (i = g, m, b)$ can be interpreted as discounted marginal (flow) values of goods, bonds, and money.[17] These can be transformed into (undiscounted) marginal values $\mu_t^i = (1+\theta)^t \lambda_t^i$ to make the role of time preference explicit. The marginal values are subjective magnitudes, measured in terms of utility.

For *consumption* the marginal conditions are

$$
\begin{aligned}
(5)\quad & \left(\frac{\partial U}{\partial x_t} - \lambda_t^g\right) x_t = 0 \\
& \frac{\partial U}{\partial x_t} \leq \lambda_t^g = \left(\frac{1}{1+\theta}\right)^t \mu_t^g \\
& x_t \geq 0
\end{aligned}
$$

If, on a given day, there is any consumption, the direct marginal utility of commodities is equal to their marginal value. Whenever the direct marginal utility is lower than the marginal value, no goods are consumed. In this case, goods are valued not because of their direct utility, but because of what they bring in exchange or through storage; their value, like the value of money and bonds, is then of an indirect nature.

For *exchange flows* the economic interpretation of the marginal conditions is also straightforward. The conditions state that exchange takes place up to the point where the marginal rate of substitution between goods (or bonds) and money is equal to their price *after transactions costs*. It is because of this wedge between market prices and marginal values, due to transactions costs, that assets may be diversified. For the same reason we have to distinguish between sales and purchases. The condition for commodities, bonds, and money are given in turn.

---

[14] Convexity can be shown to follow from the conditions for a stationary-motion equilibrium. See Section IIIB below.

[15] It should be noted that there can be no equilibrium with private debt unless both borrowing and lending are efficient at the same time. Otherwise the borrowers could find no lenders or the lenders no borrowers. The bond price would shift, swiveling the two frontiers around P, until this condition is satisfied or else the supply of private debt has disappeared.

[16] Kenneth Arrow and Alain Enthoven have shown that the Kuhn-Tucker conditions are necessary and sufficient for a maximum in a problem of this type.

[17] See M. L. Balinski and Baumol, where the required qualifications are also given.

Commodity Sales

$$(6) \qquad [(1+c^g)\lambda_t^g - p_t^g\lambda_t^m]y_t^g = 0$$

$$\frac{\lambda_t^g}{\lambda_t^m} = \frac{\mu_t^g}{\mu_t^m} \geq \frac{p_t^g}{1+c^g}$$

$$y_t^g \geq 0$$

Commodity Purchases

$$(7) \qquad [(1-c^g)\lambda_t^g - p_t^g\lambda_t^m]z_t^g = 0$$

$$\frac{\lambda_t^g}{\lambda_t^m} = \frac{\mu_t^g}{\mu_t^m} \leq \frac{p_t^g}{1-c^g}$$

$$z_t^g \geq 0$$

Whenever there is positive supply or demand, the corresponding sign becomes an equality. In the absence of transactions costs we obtain the familiar condition that whenever exchange takes place the marginal rate of substitution between goods and money is made equal to the market price. With transactions costs, the marginal rate of substitution will be higher (for sales) or lower (for purchases) than the market price. If the price *after transactions costs* is lower than the marginal rate of substitution, no sales take place. If the price after transactions cost is higher than the marginal rate of substitution, no commodities are bought. There can never be supply and demand at the same time. If strict inequalities hold for both purchases and sales, no exchange will take place on that day.

The terms λ_t^m and μ_t^m represent the ***marginal flow values of money***, discounted and undiscounted. They are flow values in the sense that they express the gain in utility resulting from a free gift of a dollar, to be used up as the individual sees fit. Satiation with cash balances, in the sense in which this term is used in the optimal money supply literature, cannot mean that λ_t^m is zero. For the individual confronted with given market prices, λ_t^m would go to zero only if λ_t^g went to zero, that is, as we approach perfect bliss. As long as there are desires, a free gift of money is always welcome. For society as a whole, with market prices variable, λ_t^m goes to zero as a progressive increase in the nominal money supply, with given λ_t^g, drives prices to infinity. Neither of these two meanings of satiation is relevant for the optimality problem, which has to do with real balances in a world of continued scarcity of resources. The relevant concept will emerge presently.

Bond Sales

$$(8) \qquad (\lambda_t^b + c^b\lambda_t^g - p_t^b\lambda_t^m)y_t^b = 0$$

$$\frac{\lambda_t^b}{\lambda_t^m} = \frac{\mu_t^b}{\mu_t^m} \geq p_t^b - c^b\frac{\mu_t^g}{\mu_t^m} = p_t^b - c^b\frac{\lambda_t^g}{\lambda_t^m}$$

$$y_t^b \geq 0$$

Bond Purchases

$$(9) \qquad (\lambda_t^b - c^b\lambda_t^g - p_t^b\lambda_t^m)z_t^b = 0$$

$$\frac{\lambda_t^b}{\lambda_t^m} = \frac{\mu_t^b}{\mu_t^m} \leq p_t^b + c^b\frac{\mu_t^g}{\mu_t^m} = p_t^b + c^b\frac{\lambda_t^g}{\lambda_t^m}$$

$$z_t^b \geq 0$$

The interpretation of the bond exchange conditions is similar to that of the commodity conditions. The only difference is that transactions costs on bonds are valued at the marginal value not of bonds, but again of commodities. This is, of course, because all transactions costs are assumed to consist of commodity inputs. If, in the given period, goods are actually sold or bought, we can substitute for μ_t^g/μ_t^m from (6) or (7) to express the condition for μ_t^b/μ_t^m in terms of market data only. The higher the transactions costs, the more likely it is that strict inequalities will appear for both sales and purchases; no bond transactions can then take place. This is the "locking in" effect of transactions costs.

The most interesting marginal conditions are those on *stocks*. They relate the marginal stock value of an asset to its opportunity cost. The marginal stock value represents the gain in utility an individual derives from *holding* a unit of an asset for one day. It is measured simply by the overnight (percentage) increase in the marginal flow value of that asset. In this way, marginal stock values are precisely related to marginal flow values. It is one of the virtues of the approach presented here that the dimensional confusion about the marginal value of money and other assets can be cleared up. The opportunity cost of an asset, on the other hand, is simply its yield, reflecting storage costs, market return, and time preference, but not including capital gains or losses due to price changes. Again, the marginal conditions can be expressed in discounted or undiscounted form. It is here where the difference becomes important, because the role of time preference as a component of asset holding costs, which is implicit in the discounted formulation, becomes explicit in undiscounted terms.

Commodity Stocks

$$(10) \qquad [(1-\gamma)\lambda_t^g - \lambda_{t-1}^g]s_t^g = 0$$

$$\frac{\lambda_t^g - \lambda_{t-1}^g}{\lambda_t^g} \leq \gamma \qquad s_t^g \geq 0$$

or

$$(10') \qquad \frac{\mu_t^g - \mu_{t-1}^g}{\mu_t^g} \leq \frac{1}{1+\theta}(\theta+\gamma)$$

Condition (10′) says that the daily valuation gain on commodity stocks, expressed as a percentage, cannot exceed the opportunity cost of commodity stocks, $\theta+\gamma$, properly discounted to the same moment. Whenever the marginal stock value of inventories is higher than their holding cost, it is profitable to increase them and equilibrium cannot yet have been reached. Conversely, if the marginal stock value is lower than the holding cost, there is an incentive to reduce the stock. However, once the stock has reached zero, no further reduction is possible and the inequality persists even in equilibrium. Walras, in developing his theory of money, postulated a special *service d'approvisionnement* for inventories. The present analysis, by explicitly relating the marginal stock value of goods to their marginal flow value, makes such constructs unnecessary.

Bond Stocks

$$(11) \qquad (\lambda_t^b - \lambda_{t-1}^b + r\lambda_t^m)s_t^b = 0$$

$$\frac{\lambda_t^b - \lambda_{t-1}^b}{\lambda_t^b} = -r\frac{\lambda_t^m}{\lambda_t^b} \qquad s_t^b \gtreqless 0$$

or

$$(11') \qquad \frac{\mu_t^b - \mu_{t-1}^b}{\mu_t^b} = \frac{1}{1+\theta}\left(\theta - r\frac{\mu_t^m}{\mu_t^b}\right)$$

The marginal stock value for bonds has the same appearance as that for commodities, expressing the daily increase in the subjective value of the bond. On the side of the opportunity cost, we are not surprised to find the coupon in the place of the storage cost rate, of course with opposite sign. The coupon rate r is weighted with μ_t^m/μ_t^b, because the coupon is paid in terms of money. It should be noted that the opportunity cost of bonds is not, as in the case of commodities and money, fixed exogenously, but through μ_t^m/μ_t^b is related to the endogenous variables of the model.

The marginal condition for bonds appears as an equality, because the individual can always make the marginal stock value equal to the opportunity cost either by holding bonds or by going into debt, thus making s_t^b positive or negative. If the bond stock is negative, the right-hand side of (11′) can be interpreted as the net marginal benefit of debt; debt permits a reduction in assets and thus in time preference costs, represented by θ, but this benefit is reduced by the interest costs. If we modify the model by excluding private debt, thus leaving only government bonds, the equality is replaced by $\leq$; once the stock is reduced to zero, nothing further can be done to raise the marginal stock value to the level of the opportunity cost.

Money Stocks

$$(12) \qquad [(1+\rho)\lambda_t^m - \lambda_{t-1}^m]s_t^m = 0$$

$$\frac{\lambda_t^m - \lambda_{t-1}^m}{\lambda_t^m} \leq -\rho \qquad\qquad s_t^m \geq 0$$

$$(12') \qquad \frac{\mu_t^m - \mu_{t-1}^m}{\mu_t^m} \leq \frac{1}{1+\theta}(\theta - \rho)$$

The marginal stock value of cash balances measures the net benefit from *holding* a dollar overnight. It can be visualized as the benefit from spending the dollar today minus the sacrifice involved in not spending it yesterday, both expressed as a percentage of today's value. While the marginal flow value of money, as pointed out above, does not go to zero for a single individual short of perfect bliss, the marginal stock value may well go to zero, indicating that larger *stocks* of money promise no further benefit. This is the satiation concept that is relevant to the problem of an optimal money supply. The opportunity cost of cash balances is simply the difference between the rate of time preference and the rate of interest on money, if any. Whenever money is held, its marginal stock value is equalized to its opportunity cost. If $\rho=\theta$, satiation with cash balances is consistent with positive cash holdings. In fact, satiation balances will then be held at all times.[18]

By relating the discounted marginal stock values for goods and money, we derive

$$(13) \qquad \frac{\dfrac{\lambda_t^g - \lambda_{t-1}^g}{\lambda^g}}{\dfrac{\lambda_t^m - \lambda_{t-1}^m}{\lambda_t^m}} = \frac{-\gamma}{\rho}$$

$$s_t^g > 0, \qquad s_t^m > 0$$

This means that the ratio between the discounted marginal stock values for goods and money, *if both are held*, is equal to the ratio between the two rates of return. A similar relationship, but in absolute terms, holds for bonds and money:

$$(14) \qquad \frac{\lambda_t^b - \lambda_{t-1}^b}{\lambda_t^m - \lambda_{t-1}} = \frac{r}{\rho}$$

$$s_t^m > 0$$

These conditions are the stock counterpart to the proposition, familiar from neoclassical flow models, that the marginal rate of substitution for any two goods is equal, in equilibrium, to the ratio of their prices. They are the exact marginal conditions for portfolio diversification.

---

[18] If $\rho=\theta$, then $\mu_t^m - \mu_{t-1}^m \leq 0$ for all t. But stationarity requires that at the end of the year this marginal stock value be at the same level as at the beginning. Thus it must be equal to zero for all t.

If there is a storage cost on commodities ($\gamma > 0$), the opportunity cost of cash balances is lower than that of commodity stocks (provided $\rho \geq 0$). Nevertheless an individual may prefer to hold commodities, because a shift into money would involve transactions cost; for short holding periods this may weigh more heavily than the saving in holding costs.[19] On the other hand, the market will see to it that the opportunity cost of bonds is lower than that of cash balances for most of the time,[20] but again transactions costs may prevent a further shift into the lower-cost asset.[21]

Neoclassical models, by introducing the money stock as an argument into the utility function, usually yield a marginal condition of the type $(\partial U/\partial M)/i = \lambda$, where $\partial U/\partial M$ represents the marginal stock utility of money (in absolute terms, not in percent), λ is the marginal utility of income, and i is the rate of interest, supposed to measure the opportunity cost of cash balances.[22] This is in close analogy to (11′). We just rewrite (11′) as

$$\frac{\overset{m}{\mu}_t - \overset{m}{\mu}_{t-1}}{\theta - \rho} \leq \frac{1}{1 + \theta} \overset{m}{\mu}_t$$

The term $(\mu_t^m - \mu_{t-1}^m)$ is seen to correspond to $\partial U/\partial M$, $(\theta - \rho)$ expresses the opportunity cost of cash balances, while μ_t^m is the marginal *flow* utility of money, analogous to the marginal utility of income. Where the neoclassical models have to *postulate* a marginal stock utility of money, the present model, by a straightforward generalization, is able to *derive* it.[23]

III. Market Equilibrium

A. *The Equilibrium Conditions*

Once we know how each individual determines his optimal plan for given prices of goods and bonds, these prices can be determined by the condition that demand equal supply in all markets. The equilibrium conditions are simple. Denoting individuals by left-hand subscripts, they can be written

$$(15) \qquad \sum_i {}_i s_t^m = M, \qquad M > 0$$

$$(16) \qquad \sum_i {}_i s_t^b = B, \qquad B \geq 0$$

$$(17) \qquad T = \rho M + rB$$

$$(18) \qquad \sum_i {}_i t_t = T$$

Equation (15) says that on each day the total demand for money must be equal to the given money stock M; equation (16) requires the same for bonds; equation (17) is the government budget constraint, stating essentially that the government's only activity consists in levying taxes to pay interest on cash balances and consols. M, B, ρ, and r are assumed to be constant over time and thus carry no time subscript. Equation (18) finally states that individual tax burdens must add up to the total required by given M, B, ρ, and r; in principle ${}_i t_t$ can be freely chosen for all but one individual. There are no equilibrium conditions for the demand and supply of commodities; if there is equilibrium for bonds and money, there is equilibrium for commodities by virtue of Walras' Law. It can easily be ascertained that an equiproportionate increase in M, r, and all ${}_ih_t$ is neutral in the sense that it results in an equiproportionate change in all commodity prices, bond prices, and money stocks, while the real variables remain unchanged.[24] The quantity theory holds.[25]

---

[19] For just two days, the relevant comparison is between slopes $-(dx_2/dx_1)^g$ and $-(dx_2/dx_1)^m$ in fn. 13.

[20] If it did not, nobody would be willing to hold bonds, and there would be a point at which it would become profitable to borrow money just to hold it idle.

[21] The exact condition for this to happen in the two-day case is obtained by comparing slopes $-(dx_2/dx_1)^m$ and $-(dx_2/dx_1)^b$ in fn. 13.

[22] See, for example, Paul Samuelson, p. 9.

[23] A similar expression for the marginal utility of money is derived by Grandmont and Younes, p. 154, by replacing the postulate of a direct utility of money by the postulate of a Cambridge-type demand function for money.

There is, of course, no general rule that money must always have a positive value in the economy of the present model. It is logically possible to conceive of a case in which each individual's endowments and tastes are synchronized in such a way that no assets and thus no cash balances are ever held. If assets are held, individuals may still be identical; as a consequence, there would be no incentive for exchange and thus no demand for a medium of exchange. Finally, even if individuals are sufficiently different, transactions costs on bonds and storage costs on goods may be so low and transactions costs on goods may be so high, that no assets are ever held in the form of money. Without transactions costs on bonds, bonds would circulate in the place of money. On the other hand, by selecting appropriate values for transactions and storage costs we can always produce asset diversification.[26] Whether a monetary economy is viable depends not on one simple condition, but on the interplay of all the factors determining equilibrium.

B. *Limiting Conditions on Market Returns*

Equilibrium requires that individuals be satisfied with finite holdings of assets and debt. We can certainly visualize market returns so high that further accumulation always pays; asset demand then becomes infinite. Equilibrium thus imposes limits on the admissible rates of asset returns.

For commodities and money, these limits are easily derived from the stationarity conditions. Stationarity is inconsistent with negative values of $(\mu_t^g-\mu_{t-1}^g)$ and $(\mu_t^m-\mu_{t-1}^m)$ for all t, because the marginal flow values would then decline from year to year. But according to the stock conditions for commodities (10′) and money (12′) these expressions would indeed be negative for all t if the respective opportunity cost, appearing on the right-hand side of (10′) and (12′), were negative. It follows that the opportunity costs must be nonnegative. There can be no positive net yield on inventories and cash balances.

The economic interpretation of this argument is straightforward. Consider money. A nonnegative opportunity cost means $\rho/\theta \leq 1$. The left-hand side measures the present value of a dollar, held forever. The right-hand side is simply the money price of a dollar. As long as the condition is satisfied, it does not pay to hold dollars forever; it only pays to hold them temporarily, when the market return is augmented by exchange services. However, if the market return on money exceeds the rate of time preference, it becomes profitable to hold cash balances permanently without ever spending them, and if this pays for one dollar, it pays for any amount. There can be no equilibrium. At the exact point where $\rho=\theta$, the economy just satiates itself with cash balances, the marginal stock values of money go to zero, the marginal flow values of money are equalized over time, and the stock demand for cash balances becomes indeterminate. The same considerations can be applied to commodity stocks. With storage costs, the limiting conditions are, of course, always satisfied. If storage costs are replaced by positive physical growth rates, resulting in a positive market return, then the limiting condition appears as the familiar rule that the growth rate must not exceed the rate of time preference.

---

[24] It can be checked that the constraints (1)–(3) and the marginal conditions (5)–(12) are not affected by such a change. The marginal flow value of money, λ_t^m, moves in inverse proportion, of course.

[25] This neutrality property depends crucially on the assumption that all money is token money.

[26] Numerical examples for a basically similar, but less general model were given in the author's 1970 paper.

The opportunity cost for bonds (or debt) differs from that for commodities and money to the extent that, in view of μ_t^m/μ_t^b, it can fluctuate over time. This means that negative opportunity costs for certain days, associated with falling μ_t^b, may be compatible with stationarity, provided they are accompanied by positive opportunity costs for other days, associated with rising μ_t^b. However, there must still be limits which bond prices cannot exceed without making equilibrium impossible. A lower limit is derived by considering bonds as an asset. To exclude infinite accumulation, the price of a bond, including transactions costs, must be at least as high as its present value, if held forever. This results in the condition

$$p_t^b + c^b \frac{\mu_t^g}{\mu_t^m} \geq \frac{r}{\theta} \tag{19}$$

The upper limit is relevant for bonds considered as a debt. To exclude an infinite amount of debt, the proceeds from selling a bond, net of transactions costs, must be no higher than the present value of the debt, maintained permanently, or

$$p_t^b - c^b \frac{\mu_t^g}{\mu_t^m} \leq \frac{r}{\theta} \tag{20}$$

These conditions must be satisfied for each individual.

While the limiting condition for money constrains the government in fixing the rate of interest on cash balances, the corresponding conditions for bonds are not a constraint on the coupon paid by the government or private borrowers. The amount of the coupon is economically irrelevant. What is limited are the possible highs and lows of the bond price. The market will automatically see to it that the limits are not exceeded. Suppose the bond price is set arbitrarily below the lower limit. Bond demand will become infinite, while the supply is finite at the level fixed exogenously by the government. It follows that the assumed price cannot be an equilibrium price; it will be bid up until it satisfies the limiting condition. The reverse is true if the bond price is set above its upper limit: there will be an infinite supply of bonds, but no demand, and the excess supply will drive the price down again.

IV. The Rate of Interest on Money and the Optimal Money Supply

Milton Friedman has proposed that the government provide for a return on cash balances equal to the rate of time preference. This proposition may fairly be called the Chicago Rule.[27] So far, its general equilibrium analysis has been fragmentary.[28] The model presented in the preceding sections can be used to shed light on its implications. It will be assumed that the return on cash balances is provided, not by deflation, but by interest payments on cash balances, financed by lump sum taxes. It will also be assumed that θ is equal for all individuals.

A. *The Demand for Cash Balances*

The first question is whether the demand for real cash balances as a function of their opportunity cost $(\theta - \rho)$ can be shown to be negatively sloped. For a year of many days it is difficult to give this question a precise meaning; real cash balances generally change from day to day, and an increase in ρ may well result in an increase in s_t^m for some days, but a decrease for others. I thus concentrate on the two-day case, considering a single individual. Any increase in real balances, achieved by the individual through an increase in nominal balances at given prices, will be achieved by the economy as a whole by a fall in prices at a given nominal money supply. It will be shown that the demand for real balances indeed rises as $(\theta-\rho)$ falls, *provided the rise in ρ is compensated by taxes.*

---

[27] See also Harry Johnson.

[28] See Hahn's critique (1971a). Grandmont and Younes take up the problem, but they make the demand for money simply a function of purchases and sales. They also do not consider credit.

We first assume that there are no bonds and that transactions and storage costs make it inefficient ever to hold commodity stocks. The transformation frontier of Figure 2 thus coincides with the money frontier; money is the only efficient asset. Figure 3 represents this case. The inner frontier with optimum Q depicts the initial situation. The demand for cash balances can be measured by $\bar{x}_1 - x_1$.[29] An uncompensated increase in ρ expresses itself by an outward rotation of the transformation frontier around P. If the new optimum is at a point like Q', cash balances rise. However, if the new equilibrium is at a point like Q'', the demand for cash balances falls.[30] The reason is that an income effect of uncertain sign is added to the positive substitution effect. If neither x_1 nor x_2 is inferior, the income effect will in fact be negative, and it may easily dominate the substitution effect. This ambiguity is familiar from the effect of changes in the rate of interest on saving.

The introduction of a compensating lump sum tax removes this ambiguity. The tax $t_2^* = \rho s_2^m$, necessary to cover the interest payments,[31] is reflected in Figure 3 in a downward shift of the transformation frontier by $(1-c^g)\ t_2^*/p_2^g$, which is the amount of day 2 consumption which could have been bought with the tax payment. The resulting equilibrium Q''' is certain to be to the left of Q.

If assets are initially held in the form of bonds and/or commodity stocks, the interest elasticity of the demand for money is further increased. In terms of Figure 2, we now start with a money frontier still inside the bond and/or commodity frontier. As ρ increases, the faces of the money frontier will swivel outward, until a point is reached at which it becomes efficient to switch from bonds or commodities into cash. The own-interest elasticity of the demand for cash balances thus depends both on the reaction of total assets and the substitution of money for other assets.

At the point where $\theta - \rho = 0$, every individual is satiated with cash balances. According to (12′), $\mu_t^m - \mu_{t-1}^m = 0$ for all t; the marginal stock values of money go to zero, while the marginal flow values are equalized over time. At the same time, the demand for real balances becomes indeterminate in the sense that individuals are indifferent to holding even higher money stocks, no matter what their amount. For the economy as a whole this means that the price level is indeterminate. The economy is in a liquidity trap, a general equilibrium counterpart to the Keynesian liquidity trap. This indifferent equilibrium is precarious, however. Any further increase in ρ would violate the stationarity condition given in Section IIIB. A stationary-motion equilibrium would no longer be possible. The stock demand for money

---

[29] From constraints (1) and (3) we derive

$$s_2^m = \frac{p_1^g}{1+c^g}(\bar{x}_1 - x_1) = \frac{1}{1+\rho}\,\frac{p_2^g}{1-c^g}(x_2 - \bar{x}_2)$$

[30] In view of the simple linear relationship

$$\frac{\lambda_2^m - \lambda_1^m}{\lambda_2^m} = 1 - \left(\frac{p_2^g}{p_1^g}\cdot\frac{1+c^g}{1-c^g}\right)\frac{\lambda_1^g}{\lambda_2^m}$$

the steeper slope of the indifference curves at the new optimum is, for given prices and transactions costs, an exact measure of the decline in the (discounted) marginal stock value of money.

[31] For the economy as a whole, the nominal money stock does not change, increases in real balances being achieved by price declines. For a representative individual, the tax thus has to cover the additional interest on the cash balance held *before* the increase in ρ.

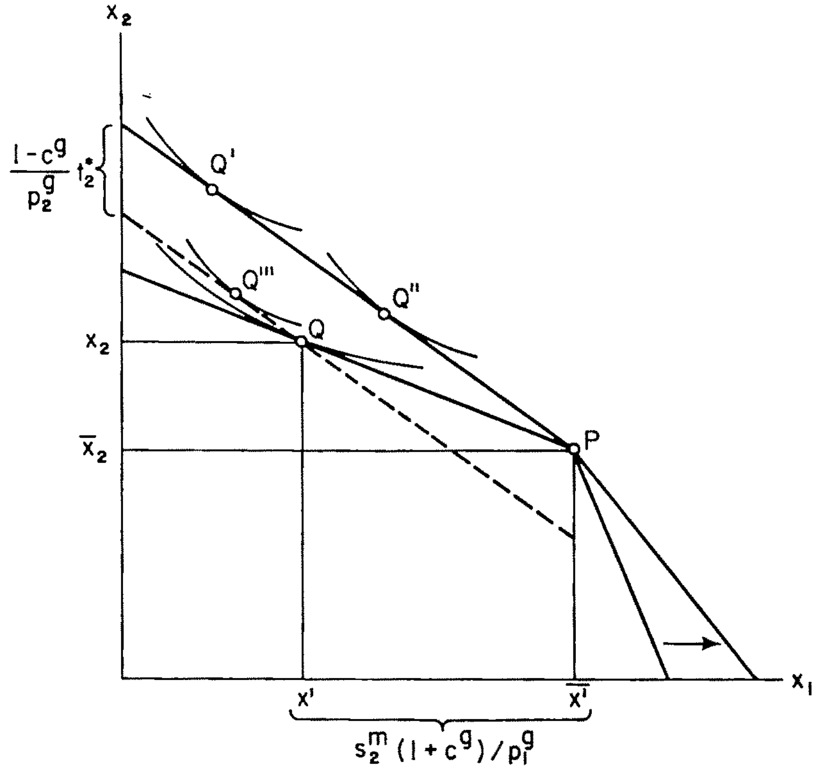

FIGURE 3

would become insatiable, and no price level above zero could provide equilibrium.[32] The Chicago Rule seems to place the economy on a knife-edge between scarcity of money and a pathological addition to higher and higher cash balances.

B. *Welfare*

The second question is whether the Chicago Rule indeed offers an increase in welfare. It offers an unambiguous increase in welfare if, and only if, an equilibrium with $\rho=\theta$ is Pareto superior to an equilibrium with $\rho<\theta$, in the sense that an increase in ρ from $\rho<\theta$ to $\rho=\theta$, all other exogenous variables remaining the same, makes some people better off without making anybody worse off.[33] Can this be shown to be the case?

Consider first a single individual confronted with given patterns of commodity and bond prices. The equalization of the marginal flow values of money means that an individual's utility can no longer be increased by offering him early a dollar he would otherwise have received later. Everybody will now behave *as if* the money constraints (3), one for each day, had been replaced by an annual budget constraint. The timing of cash flows no longer matters. This is a clear benefit, illustrated in Figure 3 by the fact that Q' and Q'' are on a higher indifference curve than Q.[34] The costs consist, of course, of the tax t_2^*. A compensated increase in ρ is analogous to the elimination of an excise tax on cash balances, financed by lump sum taxes. By the well-known argument, this makes the consumer better off; Q''' is necessarily on a higher indifference curve than Q. If prices remained unchanged, cash satiation would indeed make the economy Pareto superior.

---

[32] This is similar to the indeterminacy and nonexistence of equilibrium found by Grandmont and Younes. Feige and Parkin, p. 348, have no counterpart of this result, because they assume total wealth to be given exogenously.

[33] This question should be distinguished from the question of Pareto optimality. As is well known, Pareto optimality of state A is neither necessary nor sufficient for its Pareto superiority over some other state B. Suppose it can be shown that Pareto optimality requires $\rho=\theta$. It does not follow that, starting from a given state B with $\rho<\theta$, an increase in ρ up to $\rho=\theta$ results in a state which is Pareto superior to B. In the present context it is Pareto superiority that counts.

However, for the economy as a whole, prices cannot remain unchanged. In fact, if some prices did not decline, there could be no increase in real balances. What is more important, relative prices will also change. The conditions for a neutral change in the price level were given in Section IIIA. A compensated increase in ρ does not satisfy these conditions. It will thus affect relative commodity prices for different days of the year as well as the interest rates on bonds.[35] Nothing general can be said about the way relative prices will change. Most likely, some individuals will make additional gains, while others will lose. It would be an unlikely coincidence if some did not lose more from these price changes than they would have gained at unchanged prices. By the criterion of Pareto superiority, therefore, the Chicago Rule cannot be shown to produce an improvement in welfare.[36]

In principle, it would be possible t modify the array of lump sum taxe (possibly changing some into subsidies) i such a way that, without a further chang in aggregate T, all losers from the Chicag Rule are at least compensated by th winners. However, as long as we do no have a workable compensation schedul and have, in fact, no idea where we shoul look for the gains and losses, this is doubtful consolation.

C. *Bonds and Private Debt*

The final question concerns the implications of the Chicago Rule for the deman for bonds and the supply of private debt With cash balances having the highes yield compatible with equilibrium, i seems intuitively plausible that there ca be no incentive ever to exchange money fo bonds. One would also suspect that ther is no motive ever to go into debt. After al why should anybody borrow if he i satiated with cash at all times? These conjectures can indeed be shown to be correct

Consider first the two-day case. B comparing the slopes of the frontiers fo money and bonds, given in Section IIB for $\theta = \rho$ and substituting for the bon price (after transactions costs) from (19 and (20), it can be shown that the bon frontier cannot lie outside the mone frontier. To hold cash is always at least a good as to hold bonds. By making a simila comparison for money and debt, it ca also be shown that the debt frontier canno lie outside the money frontier. In order t shift consumption over time, it is at leas as good to accumulate the excess supply i cash as to cover the excess demand b borrowing. In the case most favorable t bonds (or debt), an individual would b just indifferent between holding cash and holding bonds (or going into debt).

---

[34] This does not mean, of course, that the shifting of resources over time is no longer costly. If the store of value consists of commodities, there are storage costs; if it consists of money, there are transactions costs on the exchange of commodities for money. The transactions frontier in Figure 2 does not become a straight line.

[35] In a multicommodity model, there would also be changes in relative prices for different commodities.

[36] In their statements about social welfare and Pareto optimality, Feige and Parkin go beyond what their model is able to support. The main reasons are that 1) they take no account of the utility of those economic agents (presumably firms) who hold those cash balance and bonds the representative household does not wan to hold at any given time, and 2) prices and interes rates are assumed to be arbitrarily fixed.

This argument can easily be generalized to n days. According to (19), the buyer of a bond pays (after transactions costs) *at least* r/θ. After n days, he can sell the bond, according to (20), for *at most* r/θ (after transactions costs). While he may make a capital loss, he cannot make a capital gain. In the best possible case, the stream of his costs and revenues will thus be $-r/\theta$, r, $r, \ldots, r+r/\theta$. If he "invests" his funds in cash, the corresponding stream is $-r/\theta$, $(r/\theta)\rho, \ldots, (r/\theta)\rho+r/\theta$. In view of $\theta=\rho$, this is identical with the best possible bond stream. In an economy satiated with cash balances, it never pays to trade bonds. If bonds are exogenously supplied by the government, they must, of course, be held. They will be held indifferently by those who happen to have them, the market pushing the rate of interest on bonds to the level of ρ. The distribution of the bonds is as indeterminate as the amount of real balances, and they are perfect substitutes for money as stores of value. For all economic purposes, they could as well be abolished.[37]

For debt the generalization is equally straightforward. Consider a marginal reduction in the amount of debt, accompanied by an equal increase in the level of cash holdings during the rest of the year.[38] This saves transactions costs on the selling and buying of bonds. At the same time, there is an increase in time preference costs over the whole year. However, this is just matched by the higher interest income over the year, consisting partly of interest earned on the additional cash balances, partly of interest saved on the debt. As long as there is any debt, a marginal shift from debt to cash holding is always advantageous. Under the Chicago Rule there is no room for private debt. Figuratively speaking, the "*Lebensraum*" of the credit market is the margin between the rate of time preference and the rate of interest on money. If this margin is compressed to zero, private credit will be squeezed out of existence.

V. Concluding Remark

By introducing transactions costs into a general equilibrium model of stationary motion, it has been possible, I believe for the first time, to explain the stock demand for inventories, cash balances, government bonds, and private debt without assigning them direct utility and without any particular assumptions about terminal stocks. The analysis was subject to two principal limitations. The first is the neglect of credit transformation and financial intermediation. To correct it, we would have to introduce various types of interest-bearing assets, each with different characteristics. Financial intermediaries would then engage in transforming one type of asset into others, of course at the cost of resource inputs. This would open the way for a general equilibrium analysis of banking. The second limitation is the lack of a detailed analysis of transactions costs. In particular, there is no analysis of the relationship between the resources used up in transactions and uncertainty. This does not reflect a lack of appreciation for the economic significance of search and information costs. It rather reflects the tactical judgement that, at the present stage of our knowledge, search processes are difficult to incorporate into a general equilibrium analysis and that the chance for progress is better if we concentrate on a world with perfect information. There is, of course, also the more fundamental difficulty of the lack of a satisfactory theory of time preference. This is a difficulty, however, for which a solution cannot fairly be expected from monetary theory.

---

[37] In the model of Feige and Parkin, money and bonds can coexist even with an "optimal" interest rate of cash balances, if the holding costs on money exceed those on bonds (equation (35)). In the present model, these holding costs are equal, both being represented by time preference. There is thus no conflict between the respective results. Of course, for models which are so different such comparisons may be questionable to begin with.

[38] In Figure 1 this corresponds to a marginal downward shift in the vertical scale.

Socially Optimal Product Differentiation

By KELVIN LANCASTER*

This paper sets out to investigate the extent to which we can reach broad general conclusions concerning the social optimality of different degrees of product differentiation. The paper is concerned with consumer preferences and production conditions only, and it abstracts from such problems as search and information costs, and disutilities of uncertainty or consumer confusion in the face of variety. It examines the problem of optimal variety in a world in which every consumer knows exactly what he prefers and exactly how to achieve personal optimality in the face of the constraints upon his actions.

Product differentiation exists when, within a group of goods so similarly related to consumers that they can be considered to form a product class, there is a variety of similar but not identical goods. The theory of product differentiation has been historically associated with the theory of monopolistic competition,[1] and has been analyzed primarily from the point of view of the firm. Although some social policy conclusions have been drawn from this approach to the subject, there does not exist a firmly based analysis leading to an answer to the question, "how many different product variants should society provide?"

One cannot go very far in answering this question within the framework of conventional or "direct" consumer theory, in which preferences are assumed to be given directly in terms of goods. For this reason, I shall turn to the "characteristics" or "indirect" analysis of consumer behavior, based on my earlier work (1966, 1971), in which the consumer is assumed to derive his actual utility or satisfaction from characteristics which cannot in general be purchased directly, but are incorporated in goods. The consumer obtains his optimum bundle of characteristics by purchasing a collection of goods so chosen as to possess *in toto* the desired characteristics.

Use of the characteristics framework provides a clear definition of a product class (those goods possessing a particular set of characteristics) and permits quantitative definition and measurement of product differentiation (by comparing the proportions in which the various characteristics are possessed by different goods within the product class), both of which properties are necessary for the analysis of optimum product variety. The characteristics framework enables us to cast the problem into a spatial setting and proceed along lines reminiscent of the pioneer work by Harold Hotelling.

The structure of the paper is as follows. First, in Section I, I shall set up some special tools of analysis that will be basic to the remainder of the analysis. Then, in Section II, I shall state and prove two basic theorems concerning optimal product differentiation and returns to scale, after which Section III examines the conditions that must be satisfied by an optimal choice for the number and type of prod-

---

[1] Chamberlin's lifelong and often pathetic struggle to retain sole title to imperfect competition should not blind us to the fact that, however the honors are to be shared between Joan Robinson and himself on the general theory of the subject, there is no doubt that it was Chamberlin who first raised the problem of the degree of product differentiation.

ucts. In Section IV, I shall state and prove four theorems concerned with optimal pricing and the effects of imperfect competition and, finally, Section V summarizes the results with special reference to policy conclusions.

The analysis will be carried out for product classes defined on two characteristics only. It will be apparent from the analysis itself and the results obtained that generalization to any number of characteristics is simply a question of additional arithmetical complexity, a complexity that does not seem justified in a pioneer investigation of the problem.

I. Tools of Analysis

A. *The Production-Consumption Link*

Consumers derive their ultimate utility or welfare from characteristics which in turn are obtained from the specific product differentiates which are available. Each product is assumed to possess those characteristics in fixed proportions. The product differentiates are themselves no more than a *transfer mechanism* by which fixed bundles of characteristics are assembled at the production end and then made available to ultimate consumers, the goods playing the role of intermediaries rather than being either primary resources or ultimate objects of consumption. If we view the system as a whole, consumer welfare is determined by the characteristics available for consumption, while the ultimate constraints are those on resources, the two linked by the transfer through goods. The transfer mechanism depends on both the way in which the resources may be used to produce goods having characteristics in different proportions and on the way in which the specific bundles of characteristics so produced are related to consumers' preferences as between all possible characteristics bundles.

For a given level of resources, the level of welfare that can be attained by the various consumers will depend on:

1) The production conditions that determine how much of each characteristic can be supplied from given resources, when embodied in a good with specific characteristics proportions.

2) The preferences of the consumers, which determine the relative welfare levels associated with various bundles of characteristics.

3) The consumption process, which determines what characteristics combinations the consumer can actually obtain from different collections of goods.

4) The number and types of goods that determine the transfer link between production and consumption.

In this paper we shall take the production and consumption possibilities as given, and be concerned primarily with the transfer mechanism. It is obvious that transfer can be efficient or not, depending on the choice of the good used for the transfer. Suppose, for example, that existing resources can be used to produce a unit of either good G_1 (embodying 2 units of characteristic z_1 and 1 of z_2) or good G_2 (1 unit of z_1, 2 of z_2). If there is a single consumer whose preferences are for high z_1-content, a lower welfare level will be attained by producing G_2 than by producing G_1. In this case, G_2 represents inefficient transfer relative to G_1, but if the consumer's preferences are biased toward z_2, the relative efficiencies of the two transfer modes will be reversed. And what if there are some consumers with preferences biased towards z_1, some towards z_2, and others in between? That is the essence of the problem we shall be solving.

B. *Production Conditions*

1. *Differentiation Possibilities*

We assume that it is possible, in principle, to produce goods having all possible ratios of the two characteristics, so that the producer can plan to produce a good anywhere in the characteristics spectrum. Having chosen the proportions in which his particular product will contain the two characteristics, there will be a unique maximum quantity of those characteristics that can be produced with given resources when incorporated in that particular good. For a given level of resources, we can take any ratio of the two characteristics, determine the maximum output of the good with that specification from the given resources and thus the maximum quantities of the two characteristics that can be produced from the resources when embodied in the appropriate good. The set of all characteristics combinations producible from a given level of resources by incorporation in a good can be plotted as a curve in characteristics space. We shall refer to this curve as a ***product differentiation curve*** and abbreviate it to *PDC*. Of particular interest will be the *PDC* corresponding to unit resource use, the ***unit PDC***.

Assume the *PDC* has geometric properties similar to those of the conventional transformation curve[2] or production possibility curve, namely: 1) it is continuous; 2) it slopes downward from left to right; 3) it is either a straight line or a curve which is concave toward the origin.

I shall make the following additional assumption: 4) *PDC*s for different resource levels are positive homothetic expansions or contractions of the ***unit PDC***. Figure 1 illustrates the assumed properties of the *PDC*s.

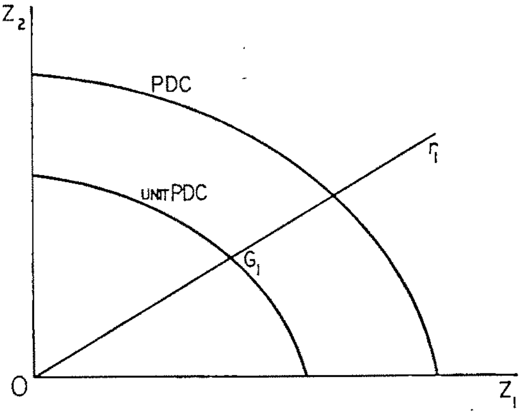

FIGURE 1

Note that I assume only a homothetic relationship between *PDC*s for different resource levels and particularly avoid any suggestion of linear homogeneity, which would imply constant returns to scale. Most of this paper is devoted to production under ***nonconstant*** returns to scale, but restricted to the homothetic case which implies the same returns to scale properties for all goods in the product class.[3]

2. *Measurement and Comparability*

The greatest single obstacle in the path of formal analysis of product differentiation is that of making quantitative comparisons between goods which are not identical. Since prices are endogenous, monetary measures cannot be used. One can only choose between comparing goods in terms of their final utility or their resource content. Since it is essential to the

---

[2] Although I referred to the *PDC* as a transformation curve in earlier versions of this paper, this is an inappropriate term. We would have a true transformation curve in characteristics space if the two characteristics were produced independently of each other, so that the curve would represent all combinations of the two separate characteristics that could be produced with given resources, each characteristic produced by its own production function with part of the total resources. Here we are concerned with the possible combinations of the two characteristics produced by incorporation in a single good. To use an analogy from high school chemistry, the regular transformation curve is concerned with ***mixtures*** of characteristics, the *PDC* with ***compounds*** made up of those characteristics.

[3] This is clearly a restrictive assumption, since it is reasonable enough to suppose that there are cases in which the returns to scale properties differ between goods in the same product class. Many of the observed differences in productivity between goods in the same product class, such as between mass-produced and custom-built automobiles, are differences in *scale* but not necessarily in the degree of *returns to scale*.

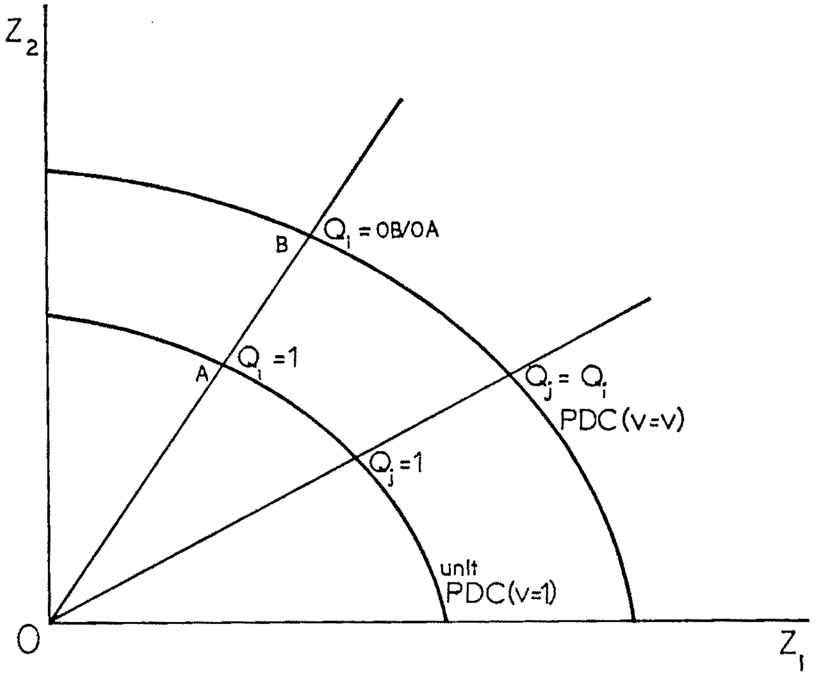

FIGURE 2

later analysis that there be many consumers with differing preferences, final utility measures are quite unsuitable. I shall, therefore, use a modified input measure that requires only that all firms face the same *PDC*s, an assumption that would be made in any case.

I shall therefore define and measure goods in the following way:

1) A good is defined by its characteristics ratio, goods with identical characteristics ratios being identical goods.

2) We bring *different* goods to the same measure by defining the unit quantity of any good to be that quantity which can be produced with unit resources.

3) Different quantities of the same good are scaled in proportion to the content of either characteristic (since the characteristics are in fixed proportions) relative to the content of that characteristic in a unit of the good as defined above.

4) As a consequence of 1)–3), plus the assumed homotheticity of the *PDC*s, quantities of different goods will receive the same measure if and only if those quantities require the same level of resources. Figure 2 illustrates the measurement system.

Note that a unit of a good is defined as requiring a unit of resources, but q units of a good do not necessarily require q units of resources since there may not be constant returns to scale. Resource content is used to relate quantities of *different* goods but quantities of the same good are scaled linearly from the resource content. Given the *unit PDC*, the characteristics content of unit quantities of different goods can be read straight off the curve and other quantities by linear scaling from these. Thus quantities of different goods are directly comparable, are in equivalent units, and can be arithmetically combined.

3. *The Input Function*

Once the choice has been made to produce a particular good with a specific characteristics ratio, there will be a defined functional relationship between the quantity of that good and the inputs required. It is convenient to use this production function in the inverse form

$$v_i = F(Q_i)$$

where v_i is the resource requirement[4] for the quantity Q_i of the good whose identity is defined by characteristics ratio $r_i (= z_2^i/z_1^i)$. I shall refer to $F(Q_i)$ as the ***input function***, to stress its inverse nature.

Due to the way in which we have defined our quantity measure and to the assumed homotheticity of the *PDC*s, F has the following very important property: ***The input function is the same for all goods. That is, the functional relationship between*** v_i ***and*** Q_i ***will be the same as the functional relationship between*** v_j ***and*** Q_j, ***for all*** i, j. (We assume, of course, that i, j are in the same product class.)

Since the input function is the inverse of a production function, $F(Q)$ increases in proportion to Q for constant returns to scale, less than in proportion for increasing returns to scale, and more than in proportion for decreasing returns. Since we shall be interested in variations in the degree of returns to scale, we note that $F(Q')/F(Q) > 1$ for all $Q' > Q$ but that the ratio approaches unity as the degree of increasing returns to scale increases without limit and the ratio increases without limit as the degree of returns to scale becomes more and more decreasing.

C. *Consumption*

1. *Consumers*

Consumers have preferences defined on characteristics. Preferences with respect to goods are indirect and derived from preferences on characteristics. These are assumed to have the same general properties with respect to characteristics as conventional preferences with respect to goods. They may be represented by preference maps with indifference curves of the conventional kind, except that we do not rule out indifference curves which are linear or piecewise linear. We shall be more interested than usual in the elasticity of substitution (curvature of the indifference curves) and sometimes concern ourselves with indifference curves showing infinite elasticity of substitution (straight lines) or zero elasticity (fixed proportions). In the latter case excess amounts of either characteristic beyond the appropriate fixed proportion will have no effect, so that zero elasticity indifference curves can be considered to extend vertically and horizontally away from the point of optimum proportions.[5]

We shall generally assume that the population consists of a very large number of consumers with different preference patterns, so that there is a continuous spectrum of preferences. Later, we shall refer to a "uniform" distribution of preferences, a term that will be defined in the appropriate context. We shall also make a special assumption about the distribution of preferences, which we introduce at the appropriate point.

2. *The Consumption Process*

Consumption involves the extraction of the characteristics embodied in the goods at the production end. There are two major technical possibilities: we may have *combinable* consumption in which goods may be combined in the consumption

---

[4] We can take the "resource" to be a single input of the dollar value of a resource mix, resource prices being taken as exogenous to the sector under consideration.

[5] Implying free disposal of the surplus characteristic, or "open satiation" as discussed in the author (1971, ch. 9).

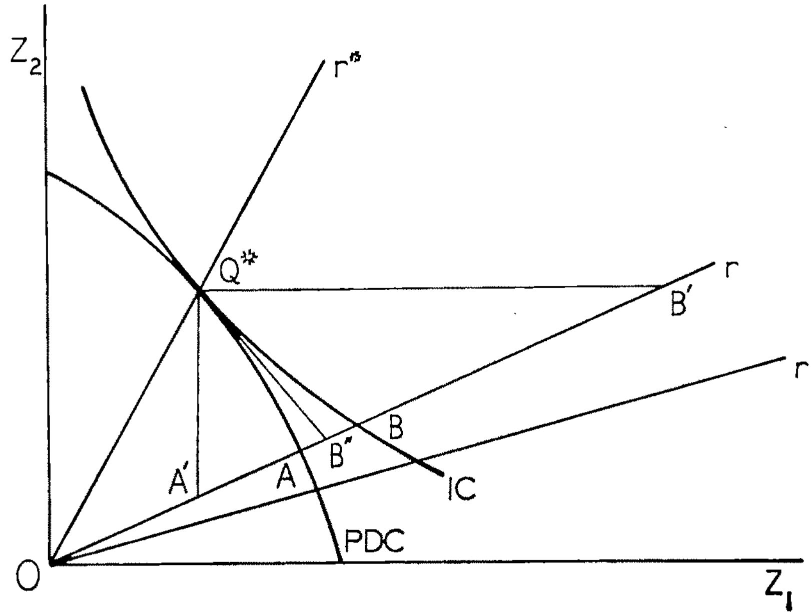

FIGURE 3

process to obtain some combination of the characteristics contents of the individual goods. Combinable consumption will be taken to be *linear*, the characteristics of the combination being the sum of the characteristics contents of the individual goods.[6] On the other hand, we may have *noncombinable* consumption in which only one good can be consumed at a time and characteristics can be obtained only in those proportions represented by an available good.

Both types of consumption are realistic in different contexts. Food nutrients fit the linear combinable case, but the services of many consumer durables fit the noncombinable pattern. The emphasis in this paper will be on noncombinable cases.

D. *Optimal and Sub-Optimal Transfer*

If we take a single individual in isolation and set out to minimize the resources required to attain a specified utility level, it is obvious which transfer good will achieve the optimum; it will be the good having a characteristics ratio r^* which corresponds to the point at which the relevant indifference curve for the consumer is tangent to a *PDC* (or at the corner of the indifference curve in the zero elasticity case). Figure 3 shows optimal transfer in diagrammatic form, and needs no further comment.

1. *Compensation for Sub-Optimal Transfer*

If the consumer's optimal good (that which would give him optimal transfer) is not available, there is some quantity of the "next best" good[7] that will enable him to achieve the utility level he would have attained with some specific quantity of the optimal good. If Q^* is the quantity of optimal good (characteristics ratio r^*) that enables the consumer to attain a specified welfare level, and Q is the quantity of a good with characteristics ratio r that enables him to achieve the same level, we can regard Q as the *compensating* quantity corresponding to Q^*. Since Q, Q^* are in comparable units, we can take the ratio Q/Q^* and refer to it as the *compensating ratio* for good r as compared with optimal good r^*.

---

[6] This is the consumption process on which my original analysis (1966) was based.

[7] It is assumed throughout the analysis that the substitution of characteristics from other product classes can be ignored, so that the "next best" good is always within the same product class as the "best" good.

Figure 3 shows a consumer for whom the optimal good is r^* and another good r ($r<r^*$) which is sub-optimal for this consumer. In order to bring the consumer to the same indifference level as attained with Q^*, he must be given an amount of good r which corresponds to point B on the diagram. From the properties of the quantity measure we are using, the compensating ratio is OB/OA.

It is obvious that the compensating ratio depends on three factors, the degree of curvature of the utility function, the degree of curvature of the *PDC*, and the difference between r and r^*. The ratio will increase with increased curvature of either curve and with an increase in the difference between r and r^*. The maximum possible value for the compensating ratio will be when B is at B' and A is at A' (corresponding to right-angled indifference and *PDC* curves with corners coincident at Q^*) and will be equal to r^*/r. In the case in which we have $r>r^*$, the maximum value of the compensating ratio will be r/r^*.

The compensating ratio will be one of the main tools of our subsequent analysis. Since it depends on r, r^* as well as on underlying preference and production conditions, it is useful to write the ratio as a function of r, r^*. We shall refer to the ratio in the form $h(r, r^*)$ as the *compensating function*, and it will have the following properties:

(1) $h(r^*, r^*)=1$

(2) $1 \leq h(r, r^*) \leq \text{Max}\,(r^*/r,\ r/r^*)$, for all r

(3) $h_r(r, r^*) \geq 0$ for $r \geq r^*$, ≤ 0 for $r \leq r^*$

(4) $h_{r^*}(r, r^*) \leq 0$ for $r \geq r^*$, ≥ 0 for $r \leq r^*$

(5) $h_{rr}(r, r^*) > 0$, unless both the indifference curve and *PDC* are linear,[8] at least for r within a "reasonable" distance of r^*.

II. Two Basic Theorems on Differentiation and Returns to Scale

Using the tools we have developed, it is possible to enunciate two basic theorems on the relationship between optimal product differentiation and returns to scale.

THEOREM 1: *If production is subject to constant or decreasing returns to scale, it will be socially optimal to produce every good which represents optimal transfer for any consumer. If and only if there are constant returns to scale in production, a linear product differentiation curve, and linearly combinable consumption processes, the social optimum can also be achieved with a number of goods in each product class not greater than the number of separate characteristics in the product class. Under decreasing returns to scale, it may be optimal to produce even more goods than under constant returns to scale with the same distribution of preferences, and certainly not less.*

Under constant returns to scale, the resources used to produce any quantity of any good are directly proportional to the quantity as measured, with the same constant of proportionality for all goods, because of the homotheticity assumption and the definition of the quantity measure. Any consumer who must consume a suboptimal good is therefore using more resources than would be needed for him to attain the same welfare level with an optimal good, and it is necessarily optimal to provide every consumer with his optimal good.

---

[8] This property may not hold for r sufficiently different from r^*, even in cases which would appear to be very well-behaved. For a linear *PDC* of the form $z_1+z_2=1$ and a Cobb-Douglas utility function of the form $u=z_1^{1/2}z_2^{1/2}$ (for which $r^*=1$), $h(r)$ has the form $h(r)=\frac{1}{2}(r^{1/2}+r^{-1/2})$, giving $h''=(3-r)/8r^{5/2}$. In this case $h''\geq 0$ only within the range $3r^*\geq r\geq 1/3r^*$.

If, in addition to constant returns to scale, there is linearly combinable consumption and a linear *PDC*, then production of the two extreme goods (each containing one of the characteristics only) will enable any consumer to attain the same welfare level by a combination of those goods as with his optimal good, for the same level of resource utilization.

Now consider the case in which there are decreasing returns to scale. In this case more goods, each produced in smaller quantities, will use less resources than fewer goods produced in larger quantities. It is obvious that it will never be optimal not to produce every consumer's optimal good. But now it may be optimal to have a consumer derive some of his welfare from a nonoptimal good, so as to reduce the average level of output of all goods.

Suppose that there is a linear *PDC* with equation $z_1+z_2=1$, and that there are two consumers whose preferences show zero elasticity of substitution and whose optimal goods are given by $r_1=3$, $r_2=1/3$. The input function has the form $v=Q^a$ ($a>1$ for decreasing returns to scale), and the consumers initially each receive one unit of their respective optimal goods for a total resource use of 2.

Now introduce a third good with characteristics ratio $r=1$, and suppose that each consumer receives some quantity of his optimal good, plus enough of the third good to bring him to his original welfare level. In this particular example the compensating ratios for the third good are equal at 1.5 and since the example is symmetrical we suppose each consumer receives an amount $(1-x)$ of his optimal good and an amount $1.5x$ of the third good, bringing each consumer to his original welfare level.[9]

Total resources used in the three-good case will then be given by

$$V = 2(1 - x)^a + (3x)^a$$

If we choose x so as to minimize V, we obtain

$$x^* = [1 + 3(3/2)^b]^{-1}$$

where $b=1/(a-1)$ which gives $x^*>0$ for all $a>1$, and thus it is optimal to produce some of the third good for all degrees of decreasing returns to scale. For $a=2$, we have $x=2/11$ and $V=18/11$, a saving of 4/11 resource units. Thus it will be optimal to produce goods which are not the optimal goods of any consumers, if there are decreasing returns to scale.[10]

It is interesting to consider the pricing associated with the above case. Since the compensating ratio is 1.5, a consumer will be induced to buy both the third good and his optimal good if the price of the third good is 2/3 that of the optimal good. Since the cost function for any good has the form $C=AQ^a$, where A is the same for all goods, we can compute the marginal costs of the goods at the optimum. It turns out that the ratio of the marginal cost of the third good to that of either optimal good is 2/3 for all values of a, when x is given its optimum value. Thus competitive prices are appropriate.

---

[9] Rather than having a single consumer with split consumption, which is somewhat unrealistic, we can suppose each "consumer" is actually an aggregate of consumers with identical tastes, some of whom consume one good and some the other.

[10] We have proved here only what we set out to do, showing that optimality under decreasing returns to scale will call for more goods than the number of distinct preferences. If decreasing returns holds for all levels of output, however small, we can continue to improve the situation by adding more and more goods (with characteristics ratios between those of existing goods) until we have a continuum of goods. If the preferences form a continuum, we will necessarily have a continuum of goods in the *constant* as well as decreasing returns cases.

A. *Increasing Returns to Scale*

Economic intuition suggests that the effect of increasing returns to scale will be to reduce the socially optimal number of goods below what it would be under constant returns to scale, at least for a sufficient degree of increasing returns. For a sufficiently well behaved case, the socially optimal number of goods will be a function of the degree of increasing returns and will decrease as this degree increases. Finally, intuition suggests that a solution for the optimal number of goods will necessarily involve solving for the optimal choice of those goods in terms of characteristics ratios. A grand theorem incorporating all these possible results is not easy to produce, so we shall start with a simple but basic theorem.

THEOREM 2: *There is some degree of increasing returns to scale, sufficiently large, for which the socially optimal number of goods is one.*

Consider a situation in which the consumers are supplied with N goods, the amount consumed of the ith good being Q_i. We make no assumptions about the specification of these goods or the distribution of preferences except that there are nonzero quantities of at least two goods. We shall consider the effect of replacing these goods by a single good, arbitrarily chosen with respect to characteristics. The quantity of the single good is denoted by Q and, if it is just sufficient to enable all consumers to attain the same welfare levels as with the N goods, it is obvious that $Q \geq \sum_1^N Q_i$. Write $Q = k\sum_1^N Q_i$, where $k \geq 1$.

We need first to prove that k is bounded above. Now, among all the consumers in the initial (N-good) situation, there must be one who consumes the greatest amount of characteristic z_1 per unit of whatever good he consumes; denote this maximal amount by $\bar{z}_1$. There will be a maximal z_2, denoted by $\bar{z}_2$, derived in a comparable fashion. Suppose the amounts of the two characteristics in unit quantity of the single good are z_1^*, z_2^* (note we restrict the single good to having some of both characteristics), then the maximal value for the compensating ratio cannot exceed $\text{Max}\,(\bar{z}_1/z_1^*, \bar{z}_2/z_2^*)$ for any consumer. The value of k cannot exceed the maximum compensating ratio for a single consumer, hence k is bounded.

Resource use in the N-good case is given by

$$V_N = \sum_1^N F(Q_i)$$

Since there are increasing returns to scale, $\sum F(Q_i) > F(\sum Q_i)$, with the ratio $\sum F(Q_i)/F(\sum Q_i)$ increasing as the degree of increasing returns increases.

If the N goods are replaced by a single good, produced in a quantity just sufficient to enable consumers to attain original welfare levels, resource use will be given by

$$V = F(Q) = F(k\sum Q_i)$$

With increasing returns, the ratio $F(k\sum Q_i)/F(\sum Q_i)$ is greater than unity, but approaches unity as the degree of increasing returns is increased without limit.

Thus we have the following situation. V_N is greater than $F(\sum Q_i)$ and recedes from $F(\sum Q_i)$ as the degree of increasing returns increases, while V is also greater than $F(\sum Q_i)$ but approaches it more and more closely as the degree of increasing returns increases. Thus there is some degree of increasing returns sufficiently great to give $V \leq V_N$, and the single good is then optimal for increasing returns of this or any greater degree, as compared with the specific N goods of the initial situation. Since no restrictions were placed on N or on the specification of the N goods, it follows that there is some degree of increasing returns for which the single good is optimal as compared with any choice of N goods, for all $N \geq 2$.

This theorem gives only a part of the overall picture with respect to increasing returns to scale, but firmly establishes the basic proposition that increasing returns will be associated with an optimal number of goods that is less than with constant returns to scale, and does this with the minimum of assumptions about preferences and their distribution or about the *PDC*.

III. The Conditions for Optimal Differentiation

Under constant returns to scale, the optimal number of product differentiates will be finite only if the number of distinct preferences represented in the society is finite, and is essentially unbounded if preferences form a continuum. Under decreasing returns to scale, the optimal number of goods will not generally be bounded even if the number of distinct preferences is finite. These are the conclusions to be drawn from Theorem 1. For increasing returns to scale, on the other hand, Theorem 2 shows the optimal number to be bounded for a sufficient degree of increasing returns. Thus the study of optimal differentiation is confined to the cases in which there are increasing returns.

Determining the optimal number of goods under increasing returns to scale is not a simple matter. We cannot merely consider the N-good case, then add an $(N+1)$th good, because there will be a total structural change in passing from N goods to $N+1$ goods. It is obvious that, since we are seeking optimality, we must find the specifications, quantities, and distribution of N goods which provide given welfare levels for minimum use of resources, then find specifications, quantities, and distribution of $N+1$ goods that achieve the same welfare levels as before for minimum resource use. In general, the goods in the $N+1$ case will be entirely different goods from those in the N-good case. The only thing that will be comparable between them will be the minimum resources required to attain the given welfare level in the two cases, and it is direct comparison of this that will indicate whether $N+1$ goods are better or worse than N. Thus solving for the optimal number of goods is a two-part process, first solving the optimum configuration for each possible number of goods, then comparing the resources required between different numbers of goods to find the optimum number. Since the number of goods is an integer variable and the configuration changes between different numbers of goods are discrete, the second stage is simple once the first has been completed.

A. *The Optimum Configuration*

The most difficult and interesting part of the overall problem is that of finding the optimum configuration for a specified number of goods. This involves finding characteristics ratios for the goods and the distribution of those goods over the consumers, such that the given welfare levels for all consumers are achieved with minimum use of resources. It is obvious that opportunities for ill behavior abound in a general model, so we shall make the two following assumptions on the distribution of preferences which are designed to give a minimum level of good behavior:

Continuum Assumption. The distribution of preferences is such that the set of all points along the *PDC* that represent optimal transfer for some individual forms a continuum.

Anticrossover Assumption. The distribution and form of preferences is such that, if it is optimal to supply two consumers whose optimal transfer goods would have characteristics ratios r_i, $r_j (\leq r_i)$ with the same good Q_k, then it will be optimal to supply Q_k to all consumers whose optimal good would have a characteristics ratio r such that $r_j \leq r \leq r_i$.

The two assumptions between them ensure that the set of all consumers being supplied with the same good is compact. It is possible to visualize cases, such as two consumers with the same optimal good, one with zero elasticity of substitution and the other with infinite elasticity, in which it just might sometimes be optimal to supply them with different goods. We rule this out by the anticrossover assumption, which implies that the shape of preferences as between individuals with closely similar optimal transfer goods does not vary too much.

To determine the optimal configuration for N goods we proceed as follows. First we note that, as a consequence of the above assumptions, the continuum of consumers (identified by the characteristics ratios of their optimal transfer goods) will be divided into N segments, each segment supplied by one of the N goods. Denote by $R_1, \ldots, R_{N-1}$ the characteristics ratios which divide the segments from each other, and by $r_1, \ldots, r_N$ the characteristics ratios of the N goods. For given preference and population distributions and given production conditions, the quantity of the ith good (characteristic ratio r_i) required to bring all consumers in the segment bounded by R_i, R_{i-1} to specified welfare levels will be a function of r_i, R_i, R_{i-1} only, so that we can write Q_i as $Q_i(r_i, R_i, R_{i-1})$.

Let us take R as given, and consider the optimal choice for r_i. Since Q_i is not a function of r_j, nor Q_j of r_i, and since R is held constant, Q_i is independent of Q_j (all i, j) and thus the optimal choice for r_i must be that which minimizes Q_i. This gives us our first optimum condition

$$(6) \qquad \partial Q_i(r_i, R_i, R_{i-1})/\partial r_i = 0$$

If Q_i^* is Q_i optimized with respect to r_i, then $Q_i^* = Q_i^*(R_i, R_{i-1})$. We can now find the optimal value for R. The Q^*, considered as functions of R, are no longer independent of each other because each R_i appears as an argument in two of the Q^*s. To optimize we must minimize total resources, given by

$$V = \sum F_i(Q_i^*) = V(R_1, \ldots, R_{N-1})$$

Because R_j appears as an argument in Q_j^*, Q_{j+1}^* only, the optimum conditions for R takes the form

$$(7) \qquad \frac{\partial V}{\partial R_i} = \frac{\partial Q_{i+1}}{\partial R_i} F'_{i+1} + \frac{\partial Q_i}{\partial R_i} F'_i = 0$$

B. *Interpretation of the Optimum Conditions*

We can give the optimum conditions an interpretation with more direct economic appeal by expressing them in terms which involve the compensating ratios. To do this we shall make the additional assumption, that *all consumers having the same optimal transfer good have identical preferences.*

Consider the segment of consumers bounded by optimal transfer ratios R_i, R_{i-1}, all supplied by good G_i with characteristics ratio r_i. Consider those consumers whose optimal good would have characteristics ratio r $(R_i \geq r \geq R_{i-1})$, and let the quantity of that good that would bring all these consumers to the specified welfare levels be denoted by $s(r)$. Since the consumers are being supplied with a good having characteristics ratio r_i, not necessarily their optimal good, the total quantity of this good needed to achieve the welfare level is given by $h(r_i, r)s(r)$, where h is the compensating function as discussed in Section I. The total quantity of good G_i required to bring all consumers in this segment up to specified utility levels is then given by

$$Q_i = \int_{R_{i-1}}^{R_i} h(r_i, r)s(r)dr$$

Since R_i, R_{i-1} appear only as limits of integration, we thus have

$$\partial Q_i/\partial R_i = h(r_i, R_i)s(R_i)$$
$$\partial Q_i/\partial R_{i-1} = -h(r_i, R_{i-1})s(R_{i-1})$$

Inserting these values in the optimum conditions (7) gives

$$\frac{F'_i}{F'_{i+1}} = \frac{h(r_{i+1}, R_i)}{h(r_i, R_i)} \tag{8}$$

Now F'_i, F'_{i+1} are the marginal resource costs of producing goods G_i, G_{i+1}, respectively. The right-hand side of (8) is the ratio of the compensating ratios for the dividing consumer (whose optimal transfer good is on the boundary between the two adjacent segments) with respect to being supplied with G_{i+1} as compared with G_i.

Thus the second optimum condition, in the case in which consumers having identical optimal transfer goods have identical preferences, has the following easily interpretable form: *The ratio of the marginal resource costs of two adjacent goods will be the inverse of the ratio of the compensating ratios with respect to the two goods, for the dividing consumer.* No special insights are given by this formulation into optimum condition (6) or into the optimality of N goods relative to M goods.

C. *A Well-Behaved Example*

To show that intuitive notions about well-behaved relationships between the optimal number of goods and the degree of returns to scale are valid in appropriate cases, we shall sketch out and give the results for a simple example.

On the production side we assume a linear *PDC*[11] of the form $z_1 + z_2 = 1$ and an input function of the form $V = Q^{1/b}$ where the degree of increasing returns increases with b. We assume that consumers show zero elasticity of substitution, have optimal goods distributed with uniform line density along the *PDC*,[12] are to be maintained on welfare levels corresponding to unit quantities of their optimal goods, and that the total population is unity.

It can be shown that, under these assumptions, the compensating function h and the density function s have the following forms:

$$\begin{aligned} h(r_i, r) &= \frac{r(1+r_i)}{r_i(1+r)} & r &\geq r_i \\ &= \frac{1+r_i}{1+r} & r &\leq r_i \\ s(r) &= \frac{1}{(1+r)^2} \end{aligned}$$

where r is the characteristics ratio of the optimal good and r_i the characteristics ratio of the good actually supplied to consumers with optimal good r.

Confining our investigations to the cases $N = 3, 2, 1$, we obtain the following optimal configurations for the three cases:

$$\begin{array}{llll} N=3: & r_1 = 1/3, & Q_1 = 7/18 & \\ & r_2 = 1, & Q_2 = 7/18 & R_1 = 1/2, R_2 = 2 \\ & r_3 = 3, & Q_3 = 7/18 & \\ N=2: & r_1 = 1/2, & Q_1 = 5/8 & \\ & r_2 = 2, & Q_2 = 5/8 & R_1 = 1 \\ N=1: & r_1 = 1, & Q_1 = 3/2 & \end{array}$$

Denoting by $V(N)$ the resources required to achieve the given utility levels with N goods of optimal configuration, we obtain $V(3) = 3(7/18)^{1/b}$, $V(2) = 2(5/8)^{1/b}$, $V(1) = (3/2)^{1/b}$. By solving for the values of b at which the various pairs are equal, we obtain our final result: The optimal number of goods is three for $b \leq 1.169$ (relative to the choice between 3 and a lesser number of goods), two for $1.169 \leq b \leq 1.263$, and one for $b \geq 1.263$. Note that the total quantity of goods ($\sum Q_i$) increases from 7/6 with three goods to 5/4 with two goods to 3/2 with one good (it is 1 for $b=1$, the constant returns to scale case). If this were not so, the optimal number of goods would never be greater than unity, if there were any degree of increasing returns.

---

[11] With a linear *PDC* we shall assume consumption is noncombinable, to rule out the possibility of achieving optimality with no more than two goods.

[12] Uniform line density is one of several possible cases of "uniform" preference distribution.

This example shows that, for a sufficiently well-behaved model, we do find the optimal number of goods decreasing steadily as the degree of increasing returns increases.[13]

IV. Four Theorems on Pricing and Imperfect Competition

The conditions for optimal configuration at the optimum number of goods lead directly to the following theorem:

THEOREM 3: *If the optimal number of goods is some number $N > 1$, then the optimal prices for those goods will be such that prices stand in the same ratio to marginal costs for all goods in the group. This can be shown to hold for any PDC, any forms of the preference functions,*[14] *and any forms for the input functions, provided there is a proper interior optimum at N goods.*

Consider the optimal distribution of the goods through a market mechanism (where each consumer has an income appropriate to the specified welfare levels), and consider the consumer whose optimal transfer good would have characteristics ratio R_i, the dividing point between the market segments supplied by G_i and G_{i+1}. If he is to be the dividing consumer, he must find that the dollar expenditures on G_i or G_{i+1} which are equivalent to a unit of his (unavailable) optimal good are the same. Thus the ratio P_i/P_{i+1} must be inverse to the ratio of the two compensating ratios $h(r_i, R_i)$, $h(r_{i+1}, R_i)$ for the dividing consumer. But we have already shown in equation (8) that the ratio of marginal costs, F_i'/F_{i+1}', must also equal the inverse of the ratio of the compensating ratios at the optimum configuration for N goods. Thus the ratio of prices between adjacent goods must equal the ratio of their marginal costs. By chain reasoning, the same relationship must then hold for all pairs of goods, proving the theorem.

Note that the theorem requires only that all prices bear the same ratio to marginal costs for goods within the group, and does not require equality of prices and marginal costs. However if we consider the group embedded in the larger economy then the usual arguments will lead to the requirement of equality in order to achieve optimality over the economy as a whole.

Equalization of the ratios of prices to marginal costs within the group is necessary but not sufficient for optimal configuration, and certainly not sufficient to guarantee that the number of goods is optimal (as we shall see in Theorem 6). It is, of course, easily possible to have the economy operating in an optimal configuration for N goods but be sub-optimal because the optimal ***number*** of goods is really M.

A. *Achieving the Optimum*

Since the interesting problems with respect to the optimum number of goods

---

[13] *A Conjecture*: The pattern of values for $\sum Q_i$ suggests that for N goods we would have $\sum^N Q_i = (2N+1)/2N$ with the optimal Q_i equal to each other at a value of $(2N+1)/2N^2$. If the conjecture were indeed true, we could then show that the value of b at which society would be indifferent between N goods and $N+1$ goods would be given by

$$b = 1 + \frac{\log\,[1 + 1/N(2N+3)]}{\log\,[1 + 1/N]}$$

This would give the lowest value of b for which the optimal number of goods would be three as 1.128 (the upper value for three goods is 1.169). The range of values for which the optimal number of goods would be ten would be $1.046 \leq b \leq 1.051$. I have not attempted to verify the truth of the conjecture.

[14] As proved, we require that all consumers with the same optimal goods have the same preferences. This can probably be relaxed.

arise with increasing returns to scale, and since the optimum pricing system is that of perfect competition, a problem arises in achieving that optimum. The competitive system will not work, first because obtaining the potential scale economies for each good requires a single producer for that good (unless the economies are all industry externalities) and, second, because all firms will make losses when price is equated to marginal cost. Furthermore, even marginal cost pricing cannot guarantee that the *number* of goods is optimal.

One possibility is a managed economy with single firm control of the production of each good and each firm constrained to adopt marginal cost pricing. This would then require a subsidy to cover the gap between total costs and total revenue for each firm. The subsidy itself would be a control variable however, since the optimum number of goods would require the minimum subsidy over the group. A subsidy set at this minimum level for the group as a whole should then induce the group to produce the optimum number of goods, given appropriate institutional rules.

B. *Imperfect Competition*

The remainder of the paper is concerned with imperfect competition and its effects on the optimal number, quantity, and specification of goods. We have different cases to consider, but in each case we shall commence from the optimum position and consider the changes introduced by the relevant type of imperfect competition. First we shall clear the air by disposing of a simple but important case.

THEOREM 4 (Constant Returns to Scale): *Under constant returns to scale, market imperfection will not cause the number or specification of goods to diverge from the optimum.*

If we commence at the optimum and there are constant returns to scale, no form of market imperfection will make it profitable for any firm to eliminate anyone's optimal transfer good because 1) there is no saving in costs from changing the number of goods produced, and 2) the maximum revenue that can be extracted from any one consumer for a given quantity of good supplied will be when he is sold his optimal transfer good. Thus the same goods will be sold, with the same characteristics ratios, as at the optimum. If there are any gains to be made by the monopolist, they will be by increasing prices and reducing quantities of the same goods which are produced at the optimum, not by changing the number of goods or their characteristics ratios. The remaining theorems are all presumed to refer to a context of increasing returns to scale.

THEOREM 5 (Single Good Monopoly): *Monopoly control of the production of any one good when firms producing other goods do not behave as monopolists will in general lead to a nonoptimal choice for the characteristics ratio of that good and, if other firms adopt marginal cost pricing, to a restriction of the output of the monopoly good.*

The second part of the theorem should surprise no one, but the first part represents a new kind of result for imperfect competition theory.

To prove the theorem, consider a particular good (characteristics ratio r) in the overall spectrum. Next to this good in the spectrum will be an "upper" good (characteristics ratio $r_U > r$) and a "lower" adjacent good (characteristics ratio $r_L < r$). The dividing consumers between the markets for the good in question and the upper and lower adjacent goods have optimal transfer goods with characteristics ratios R_U, R_L. We start from the optimal configuration and consider the changes that will be made by a monopolist taking control of the good.

We assume that over the range of variations being considered, there are no acceptable substitutes for the good from outside the group. If the price of the good increases, consumers in the center of the market will simply have to buy the same quantity of the good and spend more in order to remain at the same welfare level. Consumers at the market fringes, however, may switch to the purchase of adjacent goods if it is advantageous to do so. The market boundaries will adjust so that the dividing consumer is the one for whom the ratio of compensating ratios is inversely proportional to the price ratio. Thus the quantity of the good will be given by

$$(9) \qquad Q = \int_{R_L}^{R_U} h(r, x)s(x)dx$$
$$= Q(r, R_U, R_L)$$

where $h(r, x)$ is the compensating ratio for the consumer whose optimal good has characteristics ratio x, and $s(x)$ is the market density at x. The effect of price changes operates through changes in R_U, R_L.

By definition of the dividing ratios, the following conditions must be satisfied everywhere:

$$(10) \qquad h(r, R_U)P = h(r_U, R_U)P_U$$

$$(11) \qquad h(r, R_L)P = h(r_L, R_L)P_L$$

where P, P_U, P_L are the prices of the good in question and the upper and lower adjacent goods, respectively.

Relationships (9), (10), (11), together with the profit definition

$$(12) \qquad \pi = PQ - C(Q)$$

(where $C(Q)$ is the cost function) form a set of four relationships that must be satisfied everywhere by the six variables π, P, Q, r, R_U, R_L. There are two degrees of freedom in the system, which we shall take to be the choice of r and the choice of Q.

To prove the first part of the theorem, hold Q constant and consider the effect of variations in r on the firm's profit. Using standard comparative static methods and noting that $\partial Q/\partial r = 0$ at the optimum (optimum condition (6)), we obtain

$$(13) \qquad \frac{d\pi}{dr} = \frac{Q_L M_U h_r^L + Q_U M_L h_r^U}{Q_U M_L h^U + Q_L M_U h^L} PQ$$

at the optimum point, where

$$h^U = h(r, R_U), \qquad h^L = h(r, R_L)$$
$$h_r^U = \partial h^U/\partial r, \qquad h_r^L = \partial h^L/\partial r$$
$$M_U = \partial[Ph^U - P_U h(r_U, R_U)]/\partial R_U$$
$$M_L = \partial[Ph^L - P_L h(r_L, R_L)]/\partial R_L$$
$$Q_U = \partial Q/\partial R_U = h^U s(R_U)$$
$$Q_L = \partial Q/\partial R_L = -h^L s(R_L)$$

The h-functions always decrease as the two arguments move closer together and always increase as they diverge, so that M_U, h_r^L are positive and M_L, h_r^U are negative, while h^U, h^L are essentially nonnegative; Q_U is positive, and Q_L negative. Thus the denominator in (13) is always negative, but the numerator consists of two terms of opposite sign. Thus $d\pi/dr$ may have any sign (or be zero but only by coincidence), and the monopolist will in general find it profitable to change the characteristics ratio of his good away from the optimum.

The reason why the monopolist will not generally be satisfied with the socially optimum specification of the good is not difficult to see. From his point of view, the central consumers are locked into his market and it is only at the edges where he must compete with adjacent goods. Thus his actions in the market will be based on the properties at the market fringes, as shown by (13) where $d\pi/dr$ is seen to depend only on the properties at R_U, R_L. The socially optimal choice of r, on the other hand, is given by:

$$\frac{\partial Q}{\partial r} = \int_{R_L}^{R_U} \frac{\partial h(r, x)}{\partial r} s(x)dx = 0$$

a condition which gives weight to all consumers in the market segment.

To prove the second part of the theorem, we hold r constant and consider variations in Q. Proceeding as before, we obtain

$$(14) \qquad \frac{d\pi}{dQ} = (P - C') - \frac{QM_U M_L}{D}$$

where D is the same as the denominator in (13).

If, as assumed, we have marginal cost pricing at the optimum, then $P-C'=0$ and we have

$$(15) \qquad \frac{d\pi}{dQ} = -\frac{QM_U M_L}{D}$$

Since M_U, M_L have opposite signs and D has already been shown to be negative, $d\pi/dQ<0$ and the monopolist will find it profitable to reduce output (necessarily involving an increase in price and a shrinking of the market boundaries), completing proof of the theorem.

The next theorem is similar in its policy conclusions to the well-known "excess capacity" theorem of monopolistic competition, although it is based on a different process of reasoning and does not depend in any way on the ambiguous notion of "capacity."

THEOREM 6 (Monopolistic Competition): *Under increasing returns to scale and with a sufficiently uniform and evenly distributed market, "monopolistic competition" will lead to a greater degree of product differentiation than is socially optimal.*

Quotation marks have been placed around monopolistic competition here because one of the most basic assumptions of the Chamberlin model, that the effects of a behavior change by any one firm will be spread evenly over all other firms, most emphatically does not hold in this case. Here, the behavior of a firm affects very much those firms producing adjacent goods in the spectrum, and very little those producing goods remote from it in the spectrum. We make the remaining assumptions of monopolistic competition, that each firm produces one product, no other firm produces the same product, and there is free entry into the group that will continue so long as positive profits can be made. Thus, although the dynamics of the group cannot conform to the Chamberlin model because of the oligopolistic elements present, the equilibrium (if attained) will be of the Chamberlin kind—for a sufficiently evenly distributed total market, all firms will be of the same size, with marginal revenues equal to marginal costs and prices equal to average costs. Thus we shall consider the term *monopolistic competition* to be the most appropriate for the model being considered.

A "uniform" market is taken here to mean that, after a possible transformation of coordinates, the compensating ratio for a consumer whose optimal good has characteristics ratio corresponding to x, with respect to a good having characteristics ratio corresponding to x^*, depends only on the absolute value of the difference between x and x^*. That is, the compensating function has the particular form $h(x^*, x) = h(|x-x^*|)$. If the upper and lower dividing consumers for the market for the good represented by x^* have optimal goods with characteristics ratios x^*+c_2, x^*-c_1, and the market density is constant (taken to be unity), total demand for the good represented by x^* is given from:

$$(16) \qquad Q = \int_{x^*-c_1}^{x^*+c_2} h(|x - x^*|)dx$$
$$= H(c_1) + H(c_2)$$

where $dH/dx = h$.

Given this uniformity and uniform

density, it is obvious that goods and firms will be arranged, both at the social optimum and at monopolistic competition equilibrium, so that $c_1=c_2$ for every good, and c and Q are equal for all goods. Thus we can write $h(c)=H'(c)$ and $Q=2H(c)$ for all goods.

Since the whole spectrum is to be covered by goods with equal market areas (in the coordinates being used), there is an inverse relationship between the number of goods n, and the market area measure c, which we can write as $n=A/c$ where A is an appropriate constant.

Now consider the optimum number of goods, and suppose it is sufficiently large to treat n as closely approximated by a continuous variable. For n goods, total resource use is given by

$$V = nF(Q) \tag{17}$$

where $F(Q)$ is the input function for the single good. Since both n and Q are functions of c only, we minimize V with respect to c to obtain the condition for the optimum

$$F' = F/2ch \tag{18}$$

where the second-order conditions are satisfied for increasing returns to scale.

Having established the optimum conditions, we turn to consider the monopolistic competition equilibrium, which will consist of firms facing identical conditions. Each firm will, since we assume no oligopolistic elements and thus that other prices are taken as given, face the same considerations as the firm of Theorem 5. Due to the special uniformity assumptions, the expressions that appear in Theorem 5 have the following simplified forms here

$$h^U = h^L = h \quad (=h(c))$$

$$M_U = - M_L = 2Ph'$$

$$Q_U = - Q_L = h$$

Inserting these values in (14) of Theorem 5, together with the value of $Q(=2H)$ from above, and noting that $h=H'$, $h'=H''$, we obtain

$$\frac{d\pi}{dQ} = P - C' - 2P\frac{HH''}{(H')^2} \tag{19}$$

We shall suppose prices to be measured in resource units, so that $C=F$, $C'=F'$. We commence at the optimum and thus assume that the condition (18), $F'=F/2cH'$ is satisfied.

There are two equilibrium conditions for the monopolistic competition group: 1) that all firms are at individual profit maximizing equilibria; and 2) that there are just sufficient firms to equate price and average cost everywhere. We shall proceed by supposing that we have the socially optimal number of goods and that price is equal to average cost for all firms, then investigate whether the firms are at profit maximizing equilibria.

Inserting the values $C'=F'=F/2cH'$, $P=F/2H$, in (19) we obtain, after some manipulation,

$$\frac{d\pi}{dQ} = \frac{F}{2H'}\left[\frac{H'}{H} - \frac{H''}{H'} - \frac{1}{c}\right] - \frac{FH''}{2(H')^2} \tag{20}$$

Since H'' is positive (the compensating ratio is an increasing function of c), the last term above is clearly negative. Now consider the expression in brackets. This is equal to $d(log\ G)/dc=G'G$, where $G=H/cH'$ and is thus equal to the ratio of the average to the marginal compensating ratio over the half market from $x=x^*$ to $x=x^*+c$. Due to the assumed shape of the compensating function, G is a decreasing function of c so that G' is negative, the bracketed expression is negative, and $d\pi/dQ$ is negative.

Thus a configuration with the optimal number of goods and zero profits will not be profit maximizing for the individual firms. These can increase their profits by contracting output, leading to positive profits and the entry of more firms. The final monopolistic competition equilibrium will therefore result in a greater number of goods than at the social optimum.

Finally we shall consider the effect of monopolization of a market sector, that is control of the outputs of several goods (taken to be adjacent in the spectrum) by a single monopolist.

THEOREM 7 (Monopoly Control of a Market Sector): *Under increasing returns to scale, monopoly control of a market sector will lead to a lesser degree of product differentiation over that sector than is socially optimal.*

Consider an optimal configuration over an optimal number of goods, and consider the effect of monopoly control over several adjacent goods in the market. We shall suppose that the monopolist takes over control of the $(j-1)$th, jth and $(j+1)$th goods. Although not essential, it simplifies the argument to suppose that there is uniform distribution over this sector so that, at the social optimum, the prices of all three goods are the same.

Consider the effect of taking the jth good out of production. This will not affect those consumers who originally purchased the other two goods and, if prices are unchanged, will have no effect on consumers purchasing goods outside the monopolized sector. Since we assume throughout that there are no acceptably close substitutes for goods within the general product class from outside the class, those consumers who originally purchased the jth good will now purchase either the $(j-1)$th or the $(j+1)$th. If their incomes are fixed, they will obtain the same amount and the same quantity of the substitute as of their original good (since prices are the same), but will be somewhat worse off. If they are compensated, they will buy more of the substitute than of the original good. Thus the monopolist's average revenue will be unchanged on total sales no less than with all three goods.

Since there are increasing returns to scale, however, the increased output of the $(j-1)$th and $(j+1)$th goods will reduce average costs and thus the monopolist's profits will be increased as a result of closing down production of the jth good. Simply closing down the production of the jth good does not represent the monopolist's final equilibrium position, of course, but the profitability of this move is sufficient to prove the theorem.

V. Policy Conclusions

The policy conclusions to be drawn from the analysis can best be put in the form of answers to five questions which the policy maker must inevitably ask.

1. *Is there a socially optimal degree of product differentiation?* The answer to this basic question is yes, there is a socially optimal degree of product differentiation, divergence from which will increase the resources needed to enable consumers to attain specified levels of welfare.

2. *Can the optimum, or divergences from it, be easily recognized in the economy or in a particular industry?* The answer to this question seems, alas, to be no. Although there are clearly defined conditions that must be satisfied for the optimal configuration for a specific number of product differentiates, there are no easily recognizable conditions with respect to the actual number of goods.

3. *Would perfect competition throughout the economy result in attainment of the optimum?* The pricing system appropriate to the optimal configuration would be established under perfect competition. However, the problem of optimal differentiation is most important and most interesting under increasing returns to scale. Perfect competition, under these circum-

stances, could not take advantage of the scale economies and thus would not generate the optimum, which would require marginal cost pricing and single firm output for each good. Thus we cannot look to perfect competition to solve the optimum differentiation problem.

4. *Will market imperfections tend to give a nonoptimal degree of product differentiation?* Under constant returns to scale, no. Under increasing returns to scale, yes.

5. *Does market imperfection give a consistent bias in the degree of product differentiation, always too little or always too much?* Under increasing returns to scale, when imperfect competition tends to give nonoptimal differentiation, the direction of bias depends on the exact market structure. Monopolistic competition will lead to too much differentiation, monopolization of a market sector to too little. More complex, and thus more realistic, market structures may be expected to show effects of both kinds, leaving the direction of bias uncertain.

Security Price Changes and Transaction Volumes: Theory and Evidence

By THOMAS W. EPPS*

A familiar Wall Street adage is that transaction volume (the number of shares traded) tends to be relatively high in bull markets and low in bear markets. Although economists have long been interested in the behavior of speculative prices, they have not given adequate attention to the relation between transaction volume and price change.

Charles Ying examined the relation between the Standard and Poor's index of daily closing prices of 500 common stocks and total daily volume on the New York Stock Exchange (*NYSE*). He found that large increases in volume are usually accompanied by large price changes, that large volumes are typically associated with increases in price, and that small volumes usually accompany price declines. Unfortunately, the validity of Ying's findings has been questioned because of his adjustments on the data to account for the effects of dividends and new issues of stock over the sample period. More fundamentally, the two series that he examined (the 500-stock index and total *NYSE* volume) are not comparable.

The second criticism also applies to tests by C. W. J. Granger and Oskar Morgenstern, who found that cross-spectral analysis of weekly data showed no evidence of a relationship between the Securities Exchange Commission (*SEC*) composite price index and total *NYSE* volume. In a later paper, however, Michael Godfrey, Granger, and Morgenstern drew the same conclusion from tests on price and volume for two stocks, using individual transactions data. But none of these tests was designed to detect a relation between the volume on a transaction and the *change* in price from the previous transaction, or even between total volume and price change over an interval of time.

Their failure to detect significant correspondence between price and volume led Godfrey, Granger, and Morgenstern to question the applicability of existing theory. In their words:

> A basic problem which this analysis points out clearly is the lack of a useful theoretical framework in economics for the analysis of speculative markets . . . . It is clear that in the situation described here the volume of shares transacted bears no discernable relationship to any conventional concept of supply or demand. [p. 24]

In this paper I will show that such a theoretical framework can be constructed from a fairly broad set of portfolio-selection models and that the resulting theory implies a relationship between volume and price change on individual transactions which is in accord with the market adage stated in the opening paragraph. Specifically, the theory will be shown to imply that the ratio of volume to price change for upticks exceeds the absolute value of this ratio on downticks. The model from which this hypothesis is derived serves to bridge somewhat the gap between portfolio-selection theory and the theory of speculative prices.

I wish to express appreciation to Mary Lee Epps for writing the computer programs used in this study and to Roger Sherman for comments on an early draft. I am especially grateful to a referee for several important suggestions and to the Wilson Gee Institute for financial assistance.

Section I contains a development of the model; Section II, the empirical test; and Section III, a summary and conclusions.

I. Theory

The development of the theory is in two parts. Using a "two-parameter" portfolio-selection model as a framework, I show in Sections IA and IB that the magnitude of the intercept and slope of an individual's demand function for an asset increase with the asset's expected end-of-period value. Section IC examines the implications of this fact for market prices and transaction volumes.

A. *The Individual's Demand Function*

The following assumptions and conventions will be used:

1. Individuals base their choices among portfolios on the expected values and variances of their end-of-period values (*EPV*). The "end of the period" is some fixed moment in time.
2. An individual's utility increases monotonically with the expected *EPV* of his portfolio and decreases monotonically with its variance (risk), but the extent of his risk aversion (defined below by equation (8)) does not change with expectation and variance of *EPV*.
3. There are $n+1$ assets. Everyone considers the first n to be risky and the last one to be riskless. Strictly to simplify the exposition, we regard the riskless asset as yielding no return. (No essential property of the model is altered by this convention.)
4. There are no restraints on borrowing or selling short: individuals may freely trade claims against themselves for units of any of the $n+1$ assets.[1]
5. Anticipations about *EPV*s of assets have zero elasticity with respect to current prices.
6. Each individual considers the *EPV* of each (risky) asset to be a random variable, whose distribution changes in response to news shocks in such a way that coefficient of variation remains constant.

The last assumption requires explanation. Let $\tilde{p}_k$ be the *EPV* of the kth asset, and let p_k and S_k^2 be its expected value and variance, respectively, in the opinion of some investor. The assumption states that news which alters S_k and p_k leaves the ratio S_k/p_k unchanged. This would occur, for example, if $\tilde{p}_k$ were lognormally distributed and if news affected the mean (μ_k) but not the variance (σ_k^2) of the subjective distribution of *log* $\tilde{p}_k$. The last statement is true because lognormality implies[2]

$$p_k = \exp\left(\mu_k + \frac{\sigma_k^2}{2}\right) \tag{1}$$

$$S_k^2 = p_k^2(\exp \sigma_k^2 - 1) \tag{2}$$

so that

$$S_k/p_k = (\exp \sigma_k^2 - 1)^{1/2} \tag{3}$$

The lognormality hypothesis itself is quite plausible. Early investigators[3] of the distribution of stock prices argued that changes in the logarithm of price over intervals of time ($\Delta\, log\, P_t$) are normally distributed. While subsequent research has shown that infinite-variance distributions of the stable class and finite-variance non-Gaussian mixtures of normals usually better characterize $\Delta\, log\, P_t$, normality remains a useful hypothesis in some applications. If the distribution of $\Delta\, log\, P_t$ is regarded as approximately normal, it is reasonable to suppose that investors infer from past price behavior that changes in the logarithm of price over future periods are normally distributed as well. This implies that they regard end-of-period price as lognormal. Furthermore, if holding periods are short (so that anticipated dividend or interest payments are small relative to price), then *EPV* is approximately lognormal.

---

[1] Borrowing of cash or other assets is regarded as being accomplished in the following manner. The borrower executes an agreement with the lender to return the borrowed units of the asset at the end of the period, together with any emoluments (such as dividends) that the owner would normally receive. The borrower then trades the borrowed units for units of more preferred assets. Naturally, no new units of the asset are created on balance by the transaction—the holdings of the lender, the borrower, and the persons with whom the borrower has traded summing to the original quantity. Borrowing agreements are considered to be renegotiated at the end of each period; and periods are short enough that we may regard as negligible the risk of sufficient price fluctuation to cause default on the agreements.

[2] See J. Aitchison and J. A. C. Brown.

[3] See, for example, the papers of M. F. M. Osborne and of Arnold Moore. A reasonably complete bibliography of more recent work is given in the paper by the author and M. Epps.

B. *A Model of Investor Behavior*

The process of portfolio choice may be characterized as the search for the set of asset quantities, $a_1, a_2, \ldots a_n, a_{n+1}$, which maximizes

$$U = U(a'p + a_{n+1}, a'Sa) \tag{4}$$

subject to $W = a'P + a_{n+1}$

where 1) a, p, and P are, respectively, column vectors of the quantities, the expected *EPV*s, and the market prices of the n risky assets; 2) S is a (nonsingular) variance-covariance matrix of *EPV*s of the risky assets; and 3) W is the individual's wealth, or net worth. The first argument of U is the expected *EPV* of the portfolio; the second argument is the variance of the *EPV* (risk). Assumption 2 requires that $U_1 > 0$ and $U_2 < 0$. Assumption 3 implies that the expected *EPV* and price of the riskless asset ($n+1$) are equal, and we have arbitrarily set $P_{n+1} = 1$.[4]

The first-order conditions for a constrained maximum of U are

$$U_1 p_i + 2U_2 \sum_{m=1}^{n} a_m S_{im} - \lambda P_i = 0, \qquad i = 1, 2, \ldots, n \tag{5a}$$

$$U_1 - \lambda = 0 \tag{5b}$$

$$W - a'P - a_{n+1} = 0 \tag{6}$$

where S_{im} is the covariance between *EPV*s of the ith and mth assets. Equation (5b) gives $\lambda = U_1$. Dividing both sides of the first n equations by U_1 and solving for a yields

$$a = (\beta S)^{-1} \cdot (p - P) \tag{7}$$

where

$$\beta \equiv -2U_2/U_1 \tag{8}$$

A positive scalar, β represents the coefficient of risk aversion.

Since β is constant (by assumption 2), equation (7) provides solutions for the optimal quantities of all the risky assets. These are determined independently of the wealth constraint (6), which serves merely to specify the (positive or negative) value that must be assumed by a_{n+1}. For the kth risky asset we have

$$a_k = \frac{1}{\beta} \sum_{i=1}^{n} \frac{s_{ik}}{s} (p_i - P_i) \tag{9}$$

where s_{ik} is the cofactor of S_{ik} in S, and where s is the determinant of S. Now

$$s = r \prod_{i=1}^{n} S_i^2 \tag{10}$$

$$\frac{s_{ik}}{s} = \frac{r_{ik}}{r S_i S_k} \tag{11}$$

---

[4] The model is a fairly typical two-parameter model, resembling those of William Sharpe, John Lintner, Jan Mossin, G. O. Bierwag and M. A. Grove, and Donald Farrar. The Sharpe-Lintner models have investors maximizing preference functions of the expected value and variance (or standard deviation) of *rate* of return subject to a market constraint of attainable return-risk combinations; but despite their apparent dissimilarity to the model described here, they can be shown to be equivalent in essential respects.

where r is the determinant of the correlations matrix R, derived from S, and where r_{ik} is the cofactor of element R_{ik}. It follows from equations (9) and (11) that

$$a_k = \frac{1}{\beta} \sum_{i=1}^{n} \frac{r_{ik}(p_i - P_i)}{r S_i S_k} \tag{12}$$

The demand function specified by equation (12) may be expressed in Marshallian form:

$$P_k = p_k + S_k \sum_{i \neq k} \frac{r_{ik}(p_i - P_i)}{r_{kk} S_i} - S_k^2 \beta \frac{r}{r_{kk}} a_k \tag{13}$$

Let

$$\alpha_k \equiv 1 + \frac{S_k}{p_k} \sum_{i \neq k} \frac{r_{ik}(p_i - P_i)}{r_{kk} S_i} \tag{14}$$

$$\gamma_k \equiv S_k^2 \beta \frac{r}{r_{kk}} \tag{15}$$

By assumption 6, S_k/p_k is a constant (given by equation (3) in the case of lognormality); hence, α_k does not depend on p_k. We can write (13) more compactly as

$$P_k = \alpha_k p_k - \gamma_k a_k \tag{16}$$

Since γ_k is evidently positive, we have

$$\frac{dP_k}{da_k} = -\gamma_k < 0$$

More interestingly, γ_k (the absolute value of the slope of the demand function) is an increasing function of p_k, since equation (15) gives

$$\frac{d\gamma_k}{dp_k} = \frac{2\gamma_k}{p_k} \tag{17}$$

which is positive so long as p_k is positive.[5]

The model thus implies that an individual's demand function for a risky asset is linear and negatively sloped, and that the intercept and slope increase (in absolute value) with the asset's expected *EPV*.

C. *Implications about Market Behavior*

We introduce three additional assumptions about markets and individuals.

7. Securities markets are perfect in that 1) information is costless and transmitted instantaneously; 2) transactions are costless and can be made instantly; and 3) there are no institutional constraints upon transaction volumes or price changes.

8. An individual's interpretation of a bit of new information about a security normally depends in part on his current opinion about the asset. An individual who is bullish about a security, as a result of previous information, tends to disregard "small" bits of new information which another investor, already pessimistic about the security, regards as bearish. Similarly, the bear discounts minor information which the bull considers favorable.

9. At any moment the market for the kth asset consists of two numerically equal groups of investors, the "bulls" and the "bears," with the following characteristics: 1) each bull has a higher p_k than every bear; 2) bulls are no less risk averse than bears and no less bullish than the bears, on average, about the *other* $n-1$ risky assets; and 3) bulls and bears perceive the same correlations matrix of *EPV*s of the n risky assets and the same coefficients of variation.

The assumptions characterize the kth market as perfect and as composed of two equal groups of investors. The $J/2$ investors with the highest p_k are bulls; the rest are bears. Assumption 8 states that good news leads bulls to revise upward their expectations of the kth asset's *EPV* but that such news is ignored by bears. Bad news, while rejected by bulls, causes those who are already relatively pessimistic about p_k to lower their estimates even farther. This assumption is consistent with the observation that individuals tend to seek out, remember, and accept more readily information which reinforces their current views.

---

[5] In the case of lognormal $\tilde{p}_k$ it is easy to see also that $d\gamma_k/d\mu_k = 2\gamma_k$.

A given grouping of investors in any market is maintained so long as information is evaluated in this manner, since the flow of new information merely serves to make the bulls more bullish and the bears more bearish. We may suppose, however, that this reinforcing-interpretative behavior is abandoned temporarily under the influence of large news shocks. Shocks large enough to change opinions cause bulls and bears to break ranks and may produce entirely new groupings of investors.

From these assumptions and the theory developed in Sections IA and IB, we can now derive implications about market prices and transaction volumes. From equation (16) the demand function of the jth investor is

$$P = \alpha_j p_j - \gamma_j a_j$$

(For compactness we have dropped the subscript k, its being understood that this and subsequent expressions hold for any one of the n risky assets.) Suppose there is a total of J investors. Since the a_j may be negative (assumption 4), the market demand function is also linear. It is given by

$$(18) \qquad P = \left(\sum_{j=1}^{J} \frac{1}{\gamma_j}\right)^{-1} \sum_{j=1}^{J} \frac{\alpha_j p_j}{\gamma_j} - \left(\sum_{j=1}^{J} \frac{1}{\gamma_j}\right)^{-1} A$$

where $A \equiv \sum a_j$. Making the partial equilibrium assumption that (small) changes in the price of the asset have negligible effects on other prices, we can regard P as determined by equation (18) together with a constant supply function, $A = A_0$.

Separate demand functions can be derived for each of the two groups of investors specified by assumption 9. It will be convenient to write these functions in the following simple form:

$$(19) \qquad P = \Psi_T - \Phi_T a_T$$

$$(20) \qquad P = \Psi_U - \Phi_U a_U$$

where the subscripts T and U (from Latin) denote "bull" and "bear," respectively; where

$$(21a) \qquad \Phi_T \equiv \left(\sum_{j \in T} \frac{1}{\gamma_j}\right)^{-1} > 0$$

$$(21b) \qquad \Psi_T \equiv \Phi_T \sum_{j \in T} \frac{\alpha_j p_j}{\gamma_j}$$

and where Φ_U and Ψ_U are analogously defined. The terms Ψ_T and Ψ_U are evidently weighted averages of the intercepts, $\alpha_j p_j$, of the demand functions of individuals in the respective groups.

Equations (19) and (20) yield a new expression for market demand:

$$(22) \qquad P = \frac{\Psi_U \Phi_T + \Psi_T \Phi_U}{\Phi_T + \Phi_U} - \frac{\Phi_T \Phi_U}{\Phi_T + \Phi_U} A$$

where $A = a_T + a_U$.

From definitions (15) and (21) it can be seen that both Φ and Ψ increase under a proportional increase in p for all members of a group. From this it follows that if good news enters the market, causing an equiproportional increase in each of the p_j, $j \in T$, but not affecting the p_j, $j \in U$, then the intercept of the market demand function and the absolute value of its slope both increase. Given some stock supply function, $A = A_0$, we would expect the increase in the demand function's intercept and slope to cause, as in Figure 1, an increase in market price P.[6]

---

[6] Figure 1 also shows, however, that the increase in p would lead to a *decrease* in price if A_0 were sufficiently large. This apparent paradox can be understood by

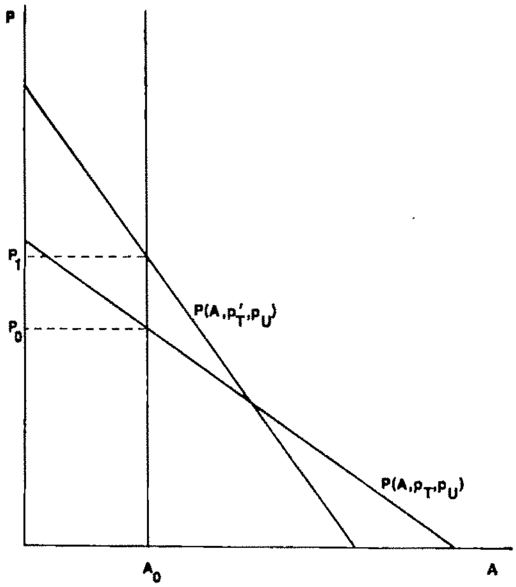

FIGURE 1. THE EFFECT OF GOOD NEWS ON MARKET DEMAND AND MARKET PRICE

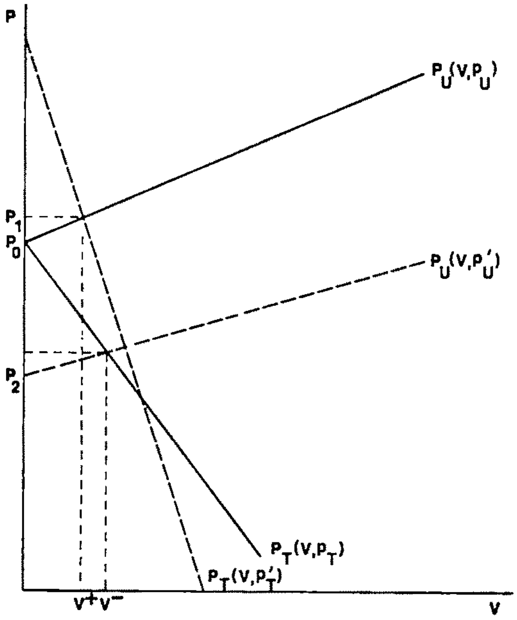

FIGURE 2. PRICE CHANGES AND TRANSACTION VOLUMES RESULTING FROM GOOD AND BAD NEWS

Equation (22) allows us to determine the effects on market price of expectational changes, but it provides no information about transaction volume. To determine the number of shares traded following a news shock, we must derive the excess demand and supply functions of the two groups of traders. The bull excess demand function and the bear excess supply function jointly determine the new equilibrium price and the volume.

The bull excess demand function and bear excess supply function from equations (19) and (20), respectively, are

$$(23) \qquad P = (\Psi_T - \Phi_T a_{T0}) - \Phi_T V$$

$$(24) \qquad P = (\Psi_U - \Phi_U a_{U0}) + \Phi_U V$$

where V represents the number of shares traded, and where a_{T0} and a_{U0} are the number of shares possessed by the two groups before trading begins. The prices corresponding to quantities in parentheses are equal to the "null" prices[7] of the two groups: the prices at which they would be satisfied with their current holdings (or, equivalently, at which excess demands and supplies would be zero). By definition, in market equilibrium each group holds the quantity at which its null price equals market price, so that

$$P_0 = \Psi_T - \Phi_T a_{T0} = \Psi_U - \Phi_U a_{U0}$$

The solid lines in Figure 2 depict the bull demand and bear supply functions in initial equilibrium. From such an equilibrium at market price P_0 we shall exam-

---

examining the demand function of a single investor (equation (13)). For large a an increase in $\hat{p}$ would so increase the asset's contribution to the risk of the individual's portfolio that he would be willing to continue to hold a units only if P were to decline. For a single investor the demand function can be shown to rotate about its midpoint when $\hat{p}$ changes. The demand curve of a group of investors can be shown also to rotate about its midpoint when $\hat{p}$ changes equiproportionately for all members of the group. Naturally, the model has descriptive value only if we regard the holdings of the groups as being small enough (in the observed range of market price) that expectational changes do not have perverse effects on quantity demanded.

[7] The term is Kenneth Boulding's.

ine alternately the effects of good and bad news on market price and volume of transactions.

Consider first a minor news shock which the bears disregard but which leads each of the bulls to revise upward his estimate of p by the factor $\delta_T > 1$. The new market price after the reestablishment of equilibrium is given by either of the following equations:

$$P_1 = (\delta_T \Psi_T - \delta_T^2 \Phi_T a_{T0}) - \delta_T^2 \Phi_T V^+ \tag{25}$$

$$P_1 = (\Psi_U - \Phi_U a_{U0}) + \Phi_U V^+ \tag{26}$$

where V^+ is the number of shares exchanged following the receipt of good news. From equation (26) the *change* in price, $\Delta P^+ \equiv P_1 - P_0$, is

$$\Delta P^+ = \Phi_U V^+ \tag{27}$$

Consequently, the ratio of transaction volume to the change in price, following the receipt of good news, is simply

$$\frac{V^+}{\Delta P^+} = \frac{1}{\Phi_U} \tag{28}$$

The volume V^+, determined from equations (25) and (26), is

$$V^+ = \frac{(\delta_T \Psi_T - \Psi_U) - (\delta_T^2 \Phi_T a_{T0} - \Phi_U a_{U0})}{\delta_T^2 \Phi_T + \Phi_U} \tag{29}$$

Next, consider the effect of bad news, starting again from the equilibrium at P_0. This time the shock is ignored by the bulls but causes each of the bears to reduce his expectation of EPV by the factor $\delta_U^{-1} < 1$. The new market price P_2 is given by either of

$$P_2 = (\delta_U^{-1} \Psi_U - \delta_U^{-2} \Phi_U a_{U0}) + \delta_U^{-2} \Phi_U V^- \tag{30}$$

or

$$P_2 = (\Psi_T - \Phi_T a_{T0}) - \Phi_T V^- \tag{31}$$

and the change in price, $\Delta P^- \equiv P_2 - P_0$, is

$$\Delta P^- = -\Phi_T V^- \tag{32}$$

The volume of transactions accompanying the downtick in price is

$$V^- = \frac{\delta_U(\delta_U \Psi_T - \Psi_U) - (\delta_U^2 \Phi_T a_{T0} - \Phi_U a_{U0})}{\delta_U^2 \Phi_T + \Phi_U} \tag{33}$$

while the ratio of volume to price change is

$$\frac{V^-}{\Delta P^-} = -\frac{1}{\Phi_T} \tag{34}$$

The behavior of the excess demand and supply functions following good and bad news is depicted in Figure 2.

Since $\Phi_T > \Phi_U$ by definitions (15) and (21) and assumption 9, equations (28) and (34) imply that the ratio of volume to price change on upticks exceeds the absolute value of the ratio of volume to price change on downticks. Stated differently, the number of shares exchanged on a transaction in which price rises exceeds the volume accompanying a price decline of the same magnitude. This implication evidently depends heavily upon the assumption that the coefficient of variation of anticipated EPV is constant. It is this assumption which implies that bulls consider assets to be riskier than bears do, and it follows from this that the bulls' demand function is steeper than that of the bears. We now turn to the testing of this hypothesis.

II. Empirical Findings

In Section IIA below we discuss the selection of a sample of securities for testing the model and explain the treatment of exceptional observations. The test itself is described in Section IIB.

A. *Selection of the Data*

The test of the model was conducted with individual transactions data, which are available in the form of volume and price for each transaction in all bonds and stocks on the two major exchanges.[8] I chose to restrict the population of securities to a set which conformed as closely as possible to the market assumptions on which the model relies. Three considerations governed the restrictions.

First, the model requires that most shocks be small enough that changes in bull and bear expectations of *EPV* do not occur simultaneously. Yet in markets where transaction costs are high, large shocks may be required to generate transactions. Harold Demsetz has argued that one component of transaction costs in securities markets, the bid-asked spread, is lower for actively traded securities than for those in which transactions occur infrequently.[9] Consequently, we should expect the proportion of transactions generated by large shocks to decline with the transaction rate. This suggests that actively traded securities should be used for our tests.

A second consideration in identifying a population of securities deals with broker commissions, the other major component of transaction costs. Fortunately, these costs are the same for sales and purchases.[10] However, distortions which would bias the test of our model are introduced by the commission schedule applying to stocks. On the leading exchanges, minimum commission rates per share increase monotonically with sale price. This causes the asked price of sellers (bears) to increase with volume at a faster rate than otherwise, and the bid price of buyers (bulls) to decline at a lesser rate than in the absence of commissions.[11] (See Figure 3.) Whether or not the distortions imposed by stock commissions are sufficient to reverse the hypothesized relation between the slopes of bull and bear demand functions is an empirical question that will be addressed in another paper. For the first test of the model, however, I avoided the problem by restricting the security population to actively traded corporate bonds. Bond commissions, with minor exceptions, are flat fees.[12] In addition, they usually constitute smaller percentages of sale prices than do commissions on stocks. Another important advantage of bond transactions data is that they are free of the influences of specialists, who, as William Baumol argues, can act (within limits) as price setters.[13]

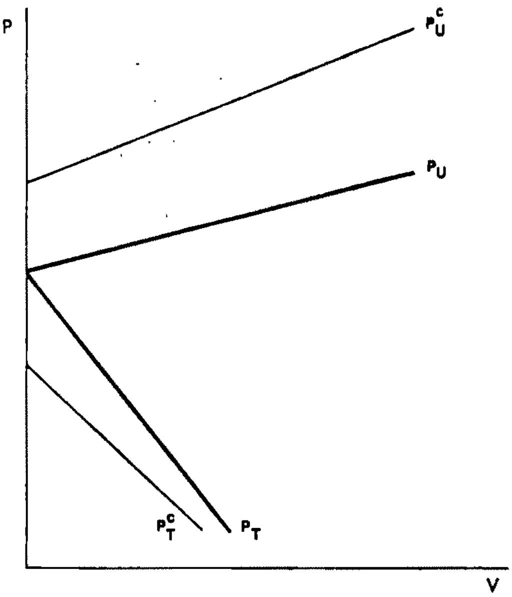

FIGURE 3. THE EFFECT OF STOCK BROKERAGE COMMISSIONS ON EXCESS DEMAND AND SUPPLY FUNCTIONS

---

[8] The data were obtained from Francis Emory Fitch.

[9] This finding is supported by the Report of the Special Study of Securities Markets, p. 75.

[10] The seller does pay, in addition to the commission, a small New York state transfer tax and an *SEC* fee which normally amount to less than .5 percent of the value of the transaction.

[11] This price effect has been offset to some degree by discounts on large stock transactions that have been in effect, in one form or another, since late 1968.

[12] The usual fee is $5 per $1000 par value. At least one major firm reduces its rate to $2.50, the *NYSE* minimum, for each bond after the first 49 traded in a single transaction. In addition, lower rates increasing by steps with price are authorized by the Exchange for bonds selling for less than $100. None of these was included in the population.

[13] On the New York Stock Exchange the most ac-

The final consideration in the choice of a population is institutional limits on transaction volume and price change. Most bond price changes occur in multiples of $\frac{1}{8}$th percent of par, and transactions occur in multiples of $1000 par value. The only apparent way to limit the possible influence of these constraints is to choose high priced, widely held bond issues, for which the minimum price change and volume constitute small percentages of market price and number of bonds outstanding.

Based on these restrictions a population of 78 securities was identified, consisting of all *NYSE* bonds with "asked" price quotations exceeding 90 percent of par and for which at least 100,000 bonds were outstanding on the first day of the sample period. A sample of 20 bonds (Table 1) was selected randomly from the population and the complete sequences of prices and volumes recorded for all transactions in each bond during the month of January, 1971.

A number of exceptional transactions in the data required special consideration. To test the model, we must distinguish transaction volumes accompanying downticks from those accompanying upticks. However, for each bond in the sample there were many transactions in which price did not change at all from its previous level. Such cases could be treated in two ways: First, transactions in which price did not change could simply be dropped from the data. Then each remaining volume could be associated unambiguously with a price uptick or downtick. Alternatively, volumes accompanying all successive transactions at a given price could be added together. Then each of the *cumulative* volumes could be identified with a downtick or an uptick.

Both ways of treating these exceptional transactions appear to have some theoretical merit, as the following argument suggests. Several phenomena can account for the occurrence of two or more successive transactions at the same price level: 1) the existence of minimum price change constraints; 2) the queuing of orders at the same bid or offer price;[14] and 3) conflicting interpretations of news that cause bull excess demand and bear excess supply curves to shift in opposite directions by

---

tively traded bonds (called "free" bonds) are bought and sold by means of verbal bids and offers made by brokers in the "crowd." Transactions in so-called "cabinet" bonds, the less active issues, are made with written bids and offers. In neither case are specialists called on to make a market. See George Leffler and Loring Farwell, pp. 273–81. For a discussion of the specialist's freedom in determining the price at which a stock transaction is made, see the Special Study of Securities Markets, especially pp. 102 and 136.

[14] These may appear on the tape as separate transactions even if the broker executes them as a group.

offsetting amounts. The last factor by itself can scarcely be responsible for many of these transactions, since it depends entirely on coincidence; but the other factors may be important. If the first factor plays an important role in bringing about successive transactions at a single price, then volumes on zero-price-change transactions should be eliminated from the data, since the transactions may have been caused by different news shocks. But if the second factor is sometimes important, successive transactions at the same price may have resulted from a *single* news shock. In this case they should all be counted as one transaction, and the cumulative volume should be used in the tests.

Since it seemed impossible to choose between the two methods for handling zero-price-change transactions, the test was conducted with both noncumulative and cumulative volume data.

B. *A Test of the Model*

The model implies that $V^+/\Delta P^+ > V^-/|\Delta P^-|$, or equivalently that $\Delta P^+/V^+ < |\Delta P^-|/V^-$. A test which compares the means of these ratios over time is ambiguous, since in a sample containing extreme values it is possible for the mean of the $V^+/\Delta P^+$ to exceed the mean of $V^-/|\Delta P^-|$ *and* for the mean of $\Delta P^+/V^+$ to exceed the mean of $|\Delta P^-|/V^-$. For this reason I employed the nonparametric Wilcoxon test to compare the centers of the distributions of $V^+/\Delta P^+$ and $V^-/|\Delta P^-|$. (See Alexander Mood and Franklin Graybill, pp. 417–19.) In samples of the sizes employed here the test yields for each bond a standard normal "z" statistic, which measures the standardized difference in the centering of the two distributions.

The z statistics for the 20-bond sample are presented in Table 2. Negative values support the theory. Sixteen of them from the tests with noncumulative volume have the correct sign; seventeen from the tests with cumulative volume. Fisher's test[15] of the combined results indicates that the probabilities of obtaining these outcomes by chance are .031 and 2.2 x 10^{-4}, respectively.

III. Summary and Conclusions

We constructed in this paper a model of securities markets which predicts with some accuracy the behavior of bond price changes and transaction volumes. The model regards all transactions as occurring between two groups of investors, the "bulls" and the "bears." Assuming that subjective probable outcomes of end-of-period value have constant coefficient of variation and that interpretations of new information typically reinforce existing opinions, the model implies that the ratio of transaction volume to price change on upticks exceeds the absolute value of this ratio on downticks. This hypothesis was strongly supported by an empirical test with individual transactions data from a sample of widely held, actively traded, high priced corporate bonds.

---

[15] The following method was employed to construct a single significance test from the 20 independent samples: if the null hypothesis is true for each of n experiments, and if α_i is the probability value (significance level) for the ith experiment, then the quantity $-2 \sum ln\, \alpha_i$ has a Chi-square distribution with $2n$ degrees of freedom. See R. A. Fisher, pp. 99–101. W. A. Wallis provides additional information about the use and applicability of this test.

Several experiments were performed to assess the sensitivity of the model to institutional constraints on price change and volume and to the presence in the data of transactions generated by large shocks. While not conclusive, the results suggested that the constraint on volume may be important. For example, in one experiment the Wilcoxon tests were repeated with a second sample of 20 bonds from another population. For this sample the average number of securities outstanding was only about 30 percent of the average for the first sample. Although these data supported the tested proposition, the results were much less convincing than those reported in Table 2.[16] Since the inability to sell or buy *fractions* of one bond presumably constitutes a greater departure from the perfect-market assumption (assumption seven) the smaller the average holding, the fact that "thinner" issues did not support proposition two as strongly may mean it is sensitive to the constraint on volume.

The sensitivity of the model suggests in turn that the slopes of the demand functions of the bullish and bearish sectors of the market do not differ markedly. Under the model's assumptions the difference between these slopes would be small if and only if there were little diversity of opinion among investors. In the United States, where corporations are required to disclose certain financial information and where advisory services disseminate this information rapidly, one suspects that the average expectations of bulls and bears are not usually far apart. In this context, it would be interesting to repeat the test of this model with pre-1934 *U.S.* data and with transactions data from a nation with highly developed financial markets but no disclosure requirement. The first test especially would provide evidence bearing on George Benston's thesis that the *SEC* Act of 1934 has done little to reduce uncertainty in financial markets.

The Measurement and Trend of Inequality: A Basic Revision

By MORTON PAGLIN*

The Lorenz curve has for some sixty years dominated our approach to the measurement of income inequality, and in consequence has become one of the most widely disseminated concepts in economics. This paper will attempt to show that a profound distortion of the degree of income inequality has resulted from the use of the Lorenz curve and the related Gini concentration ratio, both of which combine and hence confuse *intra*family variation of income over the life cycle with the more pertinent concept of *inter*family income variation which underlies our idea of inequality and economic class. To remedy the defects of the Lorenz-Gini approach, a fundamental revision is proposed which takes as its point of departure the replacement of the 45 degree line of equality with a new function generated on the basis of a more careful and explicit definition of perfect equality. This will allow us to utilize annual income data while avoiding the pitfalls now associated with its use. The widely accepted estimates of current inequality, and of historical changes in Gini ratios, are shown to have misrepresented an important characteristic of the *U.S.* economy.

I. Alternatives to Lorenzian Equality

The principal weakness of the Lorenz concept lies buried in the implications of the line of perfect equality. While a few writers have remarked that the 45 degree line has only mathematical significance, they have along with other users of the concept thrust upon it a considerable normative burden. There is really no way to avoid this if the Lorenzian area of inequality is to have any meaning as an index of income distribution. The basic fault with the existing line of equality is that it overspecifies the conditions of equality when used with annual income data. Assuming for the moment no economic growth, the maintenance of Lorenzian equality requires not only equal lifetime incomes, but additionally that families during the period of child rearing, when they have maximum income needs, must have the same incomes as families in the retirement stage of the life cycle when they have minimum economic responsibilities and maximum assets. These conditions are specified by the 45 degree line because families of all ages must have equal incomes in any given year, and this can be realized only if all families have perfectly flat age-income profiles. Yet it would be difficult to argue that a flat age-income profile is essential to equality, and there are substantial reasons for maintaining that such a mechanical requirement is itself highly inequitable. In Figure 1A, average *U.S.* family income by age of family head is indicated by curve *AB* and compared with the flat mean income profile *CD* specified by the Lorenzian equality line. It is certainly reasonable and sufficient to define perfect equality as a condition in which all families have equal lifetime incomes but traverse path AB rather than CD. In fact, to insist on flat age-income profiles flies in the face of both consumption needs and the realities of income production, for we know that investment in human resources through education and training produces a more peaked age-income profile, even apart from lifetime income differences (note Figure 2A). Lorenzian equality also does not allow family income to be increased by additional members entering the labor force. Few economists would explicitly postulate the above conditions as the requirements of perfect equality, yet this is the normative reference level embodied in the Lorenz definition. It is the standard by which we measure inequality and thereby subjectively judge the equity of our economic system.

---

* Professor, department of economics and Graduate Faculty of Urban Studies, Portland State University. Leonard Gionet and Peter Mann assisted with the statistical work and Peggy Davidson with the computer programming.

Some of the limitations of the Lorenz-Gini measure have been recognized in the literature, but the remedies suggested have taken us on a detour of data manipulation: the use of hypothetical lifetime incomes, age-group Gini coefficients, etc. However, none of these approaches has had much impact on our empirical estimates of the trend of inequality, for reasons to be discussed below. Apparently, no one has conceived of the alternative approach: reconstructing the reference line of equality to match the excellent annual income data at our disposal.

Once we cast aside the socially unrealistic 45 degree line of equality, we are free to generate new reference lines corresponding to explicit and reasonable definitions of equality, equity, or Pareto optimality. These new standards will be called P-reference lines, and in the balance of this paper one particular definition will be emphasized and used to make new estimates of inequality in the period 1947 to 1972. The new P-reference line is defined in a way which conforms to what casual users of the L curve might infer is the meaning of equality: equal lifetime incomes but not the added constraint of a

flat age-income profile.[1] While income would vary over the life cycle as indicated by curve *AB*, every family at a given stage of its life cycle would have exactly the same income as others at that stage—that is, all would have the same age-income profile. (We measure the stages of the life cycle by the age of the family head.) Now, taking the *U.S.* family population—its age distribution and average age-income profile—what would such a distribution of income look like on a Lorenz diagram? This is of course our new *P*-reference line of equality. We can derive it by taking average family income in each age group and ranking these groups by their mean incomes, remembering that every member of a group is assumed to have the same income. As expected, the young families and the over 65 age group rank at the bottom of the income scale. By using the percentage each group represents in the total population of families, a Lorenz-type curve was constructed from data in Table 1 and shown in Figure 1B as the *P*-reference line.[2] The hatched area between the 45 degree line and the *P* curve can be measured by a Gini ratio which is hereafter designated as the age-Gini. A standard Lorenz curve of family income (*L*) was then added in Figure 1B. The new area of inequality between the *P* curve and the *L* curve can also be measured by a Gini ratio which will be referred to as the Paglin-Gini, while the traditional Gini ratio based on the 45 degree line will be called the Lorenz-Gini. The Lorenz-Gini

---

[1] Equal lifetime incomes are specified in a no growth economy; with growth, the definition requires equal lifetime incomes only for members of the same age group or generation. This point is discussed below.

[2] A cubic spline function (cited in the Appendix) was fitted to the cumulative data points to derive the *P* curve.

TABLE 1

Age Group (1)	Mean Income (2)	Number of Families (thousands) (3)	Income of Group (millions) (4)	Cumulative Percent Families (5)	Cumulative Percent Income (6)

35–44	14,394	10,723	154,347	79.3	74.3
45–54	15,690	11,258	176,638	100.0	100.0
Totals		54,373	686,436		

Note: The *P*-reference curve is a Lorenz-type curve drawn up as illustrated above for 1972 family incomes (*CPR*, Series P-60, no. 90, pp. 51–53), with age groups ranked by mean incomes, not by ages.

minus the age-Gini equals the Paglin-Gini.[3]

Comparing the *P* and *L* curves in Figure 1B, and the Gini ratios of the areas shown, one is struck by the fact that fully one-third of the total area of inequality falls between the 45 degree line and the *P* curve. This shows what a large amount of ballast is included in the Lorenz-Gini measure, for clearly the age-income profile and the age structure of the population are not related to the long-run or lifetime degree of inequality in the economic system. In any case, the question of the optimum age-income profile is a different issue from that of equality as commonly conceived; our technique allows these two questions to be considered separately. Looking at the *P* curve, it is evident that rigidly egalitarian assumptions (i.e., equal lifetime incomes) may nevertheless produce a sizable area of inequality when annual income data are used. Hence, the Lorenz-Gini ratio (.359) is 50 percent greater than the Paglin-Gini (.239) which more closely approximates a measure of long-run interfamily inequality.

II. Traditional Attempts to Improve the Lorenz-Gini Measure

For some years it has been realized that the use of annual income data exaggerates the area of inequality. The suggested remedy has been the generation of hypothetical lifetime incomes since actual lifetime income data do not exist. But even if we had the data (historical and projected)

---

[3] In graphic terms, the Gini ratio is the Lorenzian area of inequality divided by the total area of the lower right triangle (Figure 1B). Algebraically, it is another measure of variance: $G = \Delta_1/2u$ where u is the mean income and

$$\Delta_1 = \frac{1}{N(N-1)} \sum_{j=1}^{n} \sum_{k=1}^{n} \{ | x_j - x_k | f_j f_k \}$$

with x representing the values of the variate and f the frequencies (see G. U. Yule and M. G. Kendall, p. 146). Δ_1 is Gini's coefficient of mean difference; it is the summation of the absolute differences between each value of the variate and every other divided by the number of such pairings. The Paglin-Gini is simply: $P.G. = (\Delta_1 - \Delta_1')/2u$ where Δ_1' equals the mean difference of the *P* curve distribution, namely, the hypothetical equality distribution in which all family incomes lie on curve *AB*. The Gini coefficient of mean difference and the concentration ratio are comparable to the more familiar measures of dispersion σ and $100\,\sigma/u$, and are monotonically related to them. Referring to Figure 1A, the Lorenz-Gini coefficient may be compared to the total variance (σ^2) around the mean, *CD*. The hatched area in Figure 1B (age-Gini) is conceptually comparable to the variance of *AB* from *CD*, while the Paglin-Gini coefficient measures the variation of values from *AB*. Education produces a greater arching of *AB* and thereby increases Lorenzian inequality which is measured from *CD*, but not the Paglin-Gini which is based on *AB*. The critique of the Lorenz-Gini measure developed here also applies to most other measures of income variation insofar as they use a single reference point such as the mean.

to construct lifetime incomes by consuming units, and converted these to constant dollars, the resulting Lorenz curve would show far more, rather than less, inequality. For in a dynamic economy with annual growth in real per capita income of 2 percent, there will be very large differences in lifetime incomes of older workers and young workers entering the labor force. With an average spread of 45 years between the new entrants and the retiring group, we can expect the former will have lifetime incomes well over 100 percent greater than the latter, and there is no practical redistribution scheme which would enable the older workers to approach the probable lifetime incomes of the younger. Also, given the upward trend in the labor-force participation rate of women, lifetime family incomes will increase even faster than the incomes of family heads. In a stationary economy, lifetime income equality is a workable hypothesis; in a growth economy, it becomes an almost unattainable goal. Therefore, to suggest that we retain the Lorenz 45 degree line but define it in terms of *lifetime* income equality gets us further from reality. While it eliminates the specification of a flat age-income profile, it saddles us with another unreasonable requirement: intergenerational lifetime income equality. This postulate, added to the empirical unreality of lifetime income data, reduces interest in this approach.

In contrast, the new P-reference function avoids these cumbersome problems. It recognizes that the past is irretrievably past, and that older generations cannot catch up with their younger contemporaries. It defines perfect equality at any point in time as equal incomes for all families at the same stage of their life cycle, but not necessarily equal incomes between different age groups. Annual income differences between age groups are solely a function of the average age-income profile; this reflects society's need for varying income over the life cycle as well as other basic facts relating to productivity, investment in human resources, and the work-leisure preferences of households, but only in an average way insofar as these factors express themselves through the age variable. The maintenance of P-reference equality posits that all members of a generation (or narrow age group) would have the same lifetime incomes; differences in lifetime incomes between generations would be mainly attributable to secular growth in real income, and such differences would be compatible with P-reference equality.

A second approach to the deficiencies of the Lorenz-Gini coefficient involves the use of age-specific Gini. The empirical coefficients available are not really specific by age of family head but in fact represent broad age groups. This introduces spurious income variance by not fully eliminating the effect of the age-income profile. However, even if we had truly age-specific Gini, we would have the problem of weighting and combining fifty-some measures into one coefficient. The use of the P curve is simpler, and allows us to graphically separate intrafamily and interfamily inequality; it also provides us with a new standard for evaluating quintile shares.

III. The Question of Consuming Units: What Should be Made Equal?

In organizing data for a Lorenz curve, the question of defining the appropriate consuming unit is usually considered a minor technical problem and hence glossed over by economists who are not specialists in this area.[4] However, the question, "What units should be made equal under perfect equality?" has substantial effects on the area of inequality, second only to redefining the equality line itself. In Table 2, the Lorenz-Gini and Paglin-Gini concentration ratios are shown for three alternative consuming units. All are based on 1972 census data, but the Lorenz-Gini coefficients vary by as much as 29 percent, for example, between "households" and "persons in families." At one extreme, the use of households (which include single person units) assumes that equality is realized if all households (no matter what their size) have the same income; at the other extreme, equality is defined in terms of persons in families, which assumes that children are equivalent to adults and that there are no economies of scale in family units. When we use persons in families instead of number of family units, the inequality coefficient decreases because family size is positively correlated with income, not inversely as commonly thought.[5] The lower income families tend to be clustered more heavily at both ends of the age-income profile where family size is below average.

---

[4] One need only refer to our leading introductory economics text (Paul Samuelson, p. 85) which after nine editions muddies the issue by using a Lorenz diagram labelled "per cent of people" to represent tabular data showing "per cent families" as the consuming unit, thus overstating the area of inequality by 13 percent.

While the Lorenz-Gini measures vary by 29 percent, the difference increases to 92 percent when we include the Paglin-Gini ratios in the comparison. Two factors account for this tremendous range (.208 to .400): 1) the alternative definitions of the equality line in terms of a flat or curved age-income profile, and 2) the question of the appropriate consuming unit—households, families, or persons? Arguments have already been given for rejecting the gross Lorenz-Gini ratios in the first column of Table 2. Of the Paglin-Gini ratios in the third column, the household figure is the least acceptable since it lumps single person units along with the larger consuming units. This leaves us with the values for "families" (.239) and "persons in families" (.208) as defining a reasonable range for net interfamily inequality in the United States. These figures are a far cry from the usually published estimates of .35 to .40 and illustrate how easily the equality issue can be overblown. A very substantial part of the traditional area of inequality (one-third to one-half) is simply a function of the diversity in the ages and size of families, and the lifetime income pattern typical of a technically advanced society. Such inequality does not represent a limitation on lifetime opportunities, nor is it a quintessential evil to be obliterated if our society is to be considered just and humane.

TABLE 2—U.S. 1972 INEQUALITY COEFFICIENTS

Consuming Unit	Lorenz-Gini	Age-Gini	Paglin-Gini
Households: includes single person units and incomes of nonfamily members living in unit.	.400	.151	.249
Families: two or more persons (excludes unrelated persons in living unit).	.359	.120	.239
Persons in families.	.320	.112	.208

IV. A Reassessment of the Trend of Inequality: 1947–1972

One major error resulting from the use of the Lorenz-Gini ratio has been the widely accepted conclusion that there has been no significant reduction of inequality from 1947 to 1972 despite the massive spending on education and training programs, the more generous cash and merit good transfers, and the legislative and judicial actions directed at bringing minor-

1972	.359	.120	.239	5.4	12.9	.419

Sources: Column (2), years 1947–64, *Trends in the Income of Families and Persons in the United States: 1947–1964*, pp. 182–87; Gini ratios for years 1965–72 were computed by the cubic-spline method from data on family income in *CPR*, Series P-60. (See Appendix for a description of the method used.) Column (3) lists the Gini ratios of the area between the 45 degree line and the *P*-reference curve computed each year from age-income data in same sources as Column (2). Column (4) equals (2) minus (3) and represents net interfamily inequality. Columns (5), (6), and (7) used the same data sources and *P* curves as columns (2) and (3).

Note: n.a. = Not available because median rather than mean incomes by age groups were given for those years.

ities and underprivileged groups into the mainstream of the economy. A fresh analysis of the income data using the *P*-reference curve indicates a considerable reduction of net inequality and a marked improvement in the share of the lowest quintile. Table 3 shows the historical data on inequality coefficients. Column (2) lists the standard Lorenz-Gini concentration ratios with only a slight decline in inequality evident. This forms the basis of the current view that inequality has not changed in the last twenty-five years. Column (3) lists the age-Gini ratios; these must be computed for each year since the age-income profile and the age structure change slowly over time. We may note a significant increase in the age-Gini from 1947 to 1972; this is related to the expansion of higher education which results in a greater arching of the average age-income profile (Figure 2), and to the increase in the percent of the aged and young adults in the population.[6]

---

[6] In 1947 young and old families (head below 25 years and over 65) together equalled 13.9 percent of all families; in 1972 they were 21.7 percent of the total.

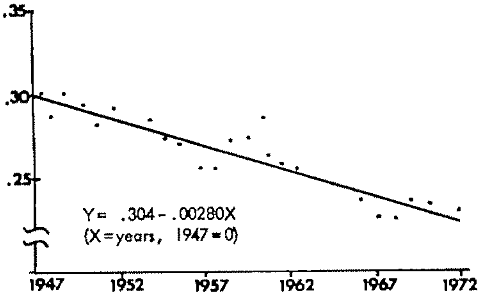

FIGURE 3A. TREND OF PAGLIN-GINI RATIOS

Note: $r=.94$; t=12.

Source for both figures: Table 3.

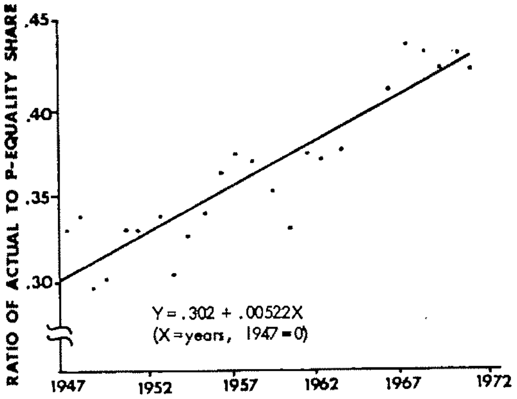

FIGURE 3B. TREND IN INCOME SHARE OF LOWEST QUINTILE USING *P*-REFERENCE CURVE

Note: $r=.91$; t=10.

Column (4) is the net measure of inequality expressed by the Paglin-Gini ratio, and is equal to column (2) minus (3). It reveals the decline in interfamily inequality of income, unobscured by changes in the age-income profile and in the age composition of the population. The least squares trend line fitted to column (4) data is shown in Figure 3A. In contrast to the traditional view, the equation indicates that inequality has declined 23 percent in the 25-year period, 1947–72.

V. Reevaluation of the Lowest Quintile

Let us consider the effect of the new equality reference line on the relative position of the lowest fifth of the income recipients. Using the traditional Lorenz curve (Table 4), the poorest families (in 1972) have 5.4 percent of the income pie whereas in a perfectly egalitarian society they would appear to get 20 percent of the income; hence it is implied that a measure of their deprivation is shown by the fact that they receive only 5.4/20 or 27 percent of the income share which would accrue to them under conditions of perfect equality. This grossly exaggerates the income deprivation of the lowest fifth. Using the more realistic definition of perfect equality embodied in our *P* curve, the relative position of the lowest quintile changes significantly, for we see that even under conditions of perfect equality of lifetime incomes (given the current age distribution and age-income profile), there would still be a "poorest" 20 percent of the families having only 12.9 percent of the income pie. Now it is appropriate to compare the 5.4 percent with the 12.9 percent, rather than with the 20 percent figure, unless we are prepared to argue that equality of lifetime income is not a reasonable norm, and that flat annual income from teenage to retirement and death is also somehow a necessary condition of equality. By employing the *P*-reference curve, we see that the poorest families receive 5.4/12.9 or 41.9 percent of the income which would accrue to them in an egalitarian utopia (Table 4). Hence, a revision of the equality norm has resulted in a 55 percent improvement in the relative assessment of the lowest income group, namely from 27 to 42 percent of the equality income share. (A similar analysis using the *P* curve as the standard results in a reduction of the share of the top

TABLE 4—1972 FAMILY INCOMES: LORENZ AND *P* CURVE EQUALITY COMPARISONS

Quintiles	Percent of 1972 Income (Actual)	Perfect Equality Lorenz Shares	Perfect Equality Shares Using *P* Curve	Actual Income Share as a Percent of: Lorenz Share	Actual Income Share as a Percent of: *P*-Curve Share
Lowest	5.4	20	12.9	27.0	41.9
2	11.9	20	17.8	59.5	66.9
3	17.5	20	21.5	87.5	81.4
4	23.9	20	22.9	119.5	104.4
Highest	41.3	20	24.9	206.5	165.9

Source: CPR, Series P-60, no. 90. *P*-equality shares interpolated from cubic-spline curve fitted to *P*-curve data points.

quintile from 2.07 times to 1.66 times the equality share, see Table 4.)

We may now begin to understand why the poorest 20 percent historically seem to be so resistant to improvements in terms of the conventional Lorenz curve analysis: to a large degree, the low percentage of the income pie going to this group is a built-in result of the age-income profile coupled with the age distribution of the population, and is not purely related to the condition of a permanent class of people excluded from the average level of real income enjoyed by most families. This has profound implications, for the failure to understand the nature and extent of economic inequality has led to a distorted assessment of our economic system.

This distortion has been further amplified by a statistical decision to exclude need-based in-kind transfers from the definition of income. As a matter of social policy, we have decided to mitigate poverty by making large transfers in the form of public housing, rent supplements, food stamps and food assistance, medicaid, and social services such as day care, etc. We then blithely exclude these transfers from the statistics on poverty and inequality and wonder about the lack of improvement in the share allotted to the lowest quintile! Fifteen years ago, in-kind transfers were small and could be overlooked, but now they exceed the cash allotments and are growing at a much faster rate. In fiscal year 1973, expenditures on the major income-tested transfer programs (federal, state, and local) totaled $30.7 billion of which 55 percent or $16.9 billion were in-kind transfers. While the cashing out of in-kind transfers is a complex task which will be dealt with in a subsequent article, a loose estimate of their distributive impact can be made. Since we are focusing on family units, only 80 percent of the in-kind transfers or $13.5 billion is applicable. Now assume that 20 percent of the $13.5 billion goes for administration. This leaves $10.8 billion as an addition to the income of the bottom quintile, boosting its 1972 income share from 5.4 to 7.0 percent. Hence if in-kind transfers are included as income, the lowest quintile has about 54 percent of the *P* curve equality share of 12.9 percent.[7]

Aside from the sharp increase of in-kind transfers which characterized the period 1947–72, the historical position of the lowest quintile purely in terms of money income has improved significantly. While this improvement has been obscured by the crude Lorenz approach (Table 3, column (5)), it is revealed by comparing in each year the actual share received by the lowest quintile with the *P* curve equality share. These ratios are shown in Table 3, column (7), and are plotted in Figure 3B along with the least squares trend. We may conclude that the overall reduction of inequality in the period 1947–72 has been accompanied by an upward trend in the money income share of the lowest quintile, namely, from 33 to 42 percent of the equality share.

---

[7] The data on transfer programs are derived from *The Budget of the U.S. Government, FY 1975, Appendix,* pp. 203–05, 440–42, 494, and 808. Programs such as medicare, which affect many low income families, have been excluded from the totals because they are not income tested. The 80 percent figure represents the proportion of low income persons living in families (*CPR,* no. 98, p. 13). The 20 percent for administrative costs is a rough estimate which may be low for existing programs but would be too high if a cash transfer strategy (negative income tax) were used.

VI. Wealth Inequality

From income inequality let us move on to the distribution of wealth. Our criticisms with some modification also apply to the Lorenz-Gini wealth coefficient. Simply stated, the problem is this: the 45 degree line of equality requires that wealth holdings among families be equal regardless of the age of the head of household. Given a typical age distribution of the population, this means that cumulative annual saving, plus interest compounded, can have no effect on individual family wealth. Again, this is an added specification which most persons would consider an unnecessary and unrealistic constraint even in an egalitarian society. It would seem sufficient to define equality as a social condition in

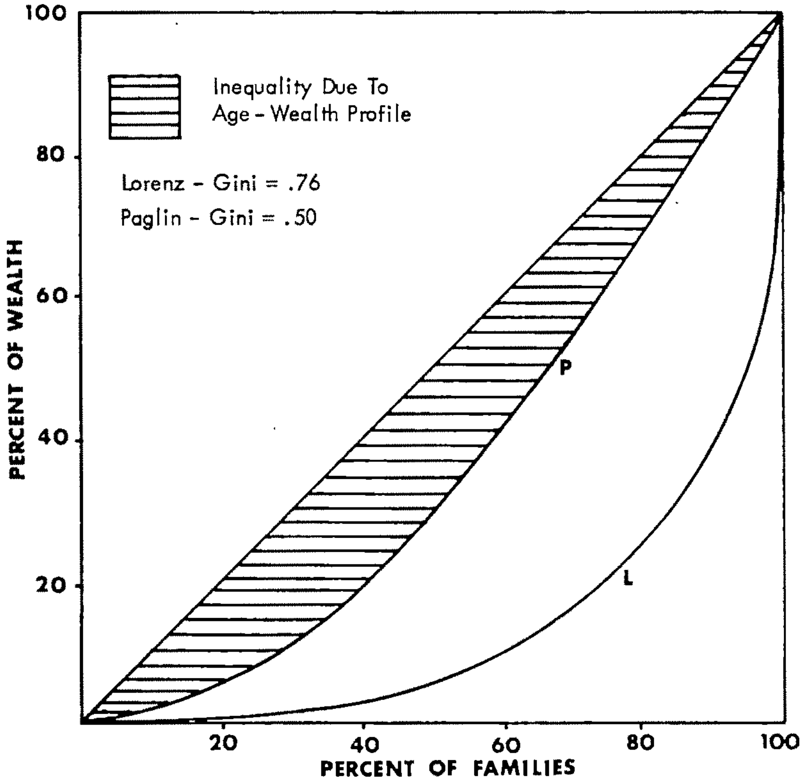

FIGURE 4. *U.S.* DISTRIBUTION OF WEALTH, 1962

Source: Projector and Weiss, pp. 110, 151.

which inheritance of wealth is not a significant factor in the *relative* distribution of wealth, all lifetime incomes (for a given generation) are equal, and family wealth is a function mainly of saving and time, with everyone having the same rate of saving (or dissaving) at a given stage of the life cycle. These assumptions would produce equality of wealth for families in the same age bracket, but would allow differences of wealth based on age. With this definition, what would a P-reference function for the United States look like, using the average age-wealth profile derived from Federal Reserve Board data (see Dorothy Projector and Gertrude Weiss)? The results are shown in Figure 4. The area between the 45 degree line and the P-reference function is hatched, and the Lorenz curve of wealth is also shown. It is apparent that a significant percentage of the total area of inequality (about one-third of it) would exist even in a rigidly egalitarian society, and therefore, this segment of wealth inequality reflects the age structure and the social savings function rather than fundamental (lifetime) inequality in the economic system. For the United States (in 1962) the Lorenz-Gini of wealth was .76 compared with a Paglin-Gini of .50; hence, the traditional measure has overstated the degree of interfamily inequality of wealth by about 52 percent.

VII. Summary and Conclusion
